Examination should include both lower extremities, though post-treatment examinations may target a single extremity or a single area of an extremity. The full length of the axial venous system from ankle to groin is examined. The probe is aligned transversely so that specific named veins can be identified and their relations to other limb structures determined. The veins are scanned by moving the probe up and down along their courses. Double segments, sites of tributary confluence, and large perforating veins (along with their deep venous connections) are identified. (Perforating veins are those that course from the subcutaneous tissue through deep fascia to anastomose with one of the named deep venous structures; communicating veins are those that anastomose with one another within a single anatomic plane.) Varicose veins are often arranged in multiple parallel channels. It is unnecessary to follow reflux into all of the varicose clusters, because these are obvious to the treating physician. Augmentation of flow (distal compression) is done sharply, quickly, and aggressively, and pressure is applied to the calf to activate the gastrocnemius-soleus pump. When a color or pulsed-wave Doppler device is used, the probe is angled to provide an insonation angle of 60° or less.

For the anterior examination, the patient faces the sonographer with his or her weight borne on the lower extremity that is not being examined. The non-weight-bearing extremity is then evaluated. The common femoral vein and the saphenofemoral junction are assessed with the Valsalva maneuver and with distal compression and release. If reflux is present, the diameter of the refluxing GSV is not-

ed for subsequent use in selecting the proper endovenous catheter during saphenous ablation.

The GSV is identified on the basis of its relation to the deep and superficial fascia that ensheathes it to form the saphenous compartment. High-resolution B-mode ultrasonographic imaging of the superficial fascia in the transverse plane has shown that this structure reflects ultrasound strongly, yielding a characteristic image of the GSV known as the saphenous eye [see Figure 1]. The saphenous eye is a constant marker that is clearly demonstrable in transverse sections of the medial aspect of the thigh and that readily differentiates the GSV from varicose tributaries and other superficial veins. Casual examination of the thigh often reveals an elongated, dilated vein that is incorrectly assumed to be the GSV. This mistaken assumption can be corrected by means of ultrasound scanning with the saphenous eye as an anatomic marker.

Venous reflux can be elicited manually by calf muscle compression and release, by the Valsalva maneuver, or by pneumatic tourniquet release. In terms of efficacy, there is no difference between pneumatic tourniquet release and manual compression and release. However, pneumatic tourniquet release is cumbersome and requires two vascular sonographers, which makes the manual compression and release method very attractive by comparison. If saphenofemoral reflux lasting longer than 0.5 second is present, the diameter of the GSV is recorded 2.5 cm distal to the saphenofemoral junction.

The examination continues distally along the GSV, with distal augmentation of flow performed at intervals to check for reflux. Reflux frequently ends in the region of the knee. The point at which reflux stops is recorded in terms of distance from the floor in centimeters. The femoral vein (i.e., the vessel formerly termed the superficial femoral vein) is checked at midthigh for reflux and vein wall irregularities.

The posterior examination is also done on the non-weight-bearing lower extremity, with attention paid to reflux in the popliteal vein, the saphenopopliteal junction, and the SSV. The Valsalva maneuver may be used to stimulate reflux, as may distal augmentation and release. Valsalva-induced reflux is halted by competent proximal valves. The SSV is followed from its retromalleolar position on the lateral aspect of the ankle proximally to the saphenopopliteal junction, and augmentation maneuvers are performed every few centimeters.

The termination of the SSV is noted. If the vein terminates proximally in the vein of Giacomini, the femoropopliteal vein, or another vein, a specific check is made for a connection to the popliteal

vein. If the SSV shows reflux, the distance from the saphenopopliteal junction to the floor is measured and recorded.

A search for incompetent perforating veins is necessary only in limbs with chronic venous insufficiency (CVI) manifested by hyperpigmentation, atrophie blanche, woody edema, scars from healed ulceration, or actual open ulcers. Incompetent perforating veins in limbs without CVI are associated with varicose veins and can be controlled with varicose phlebectomy. Identification of perforating veins in the lower extremity can be difficult even for the experienced sonographer.

Procedural Planning

For varicose vein treatment to be successful, two goals must be met: (1) reflux must be ablated from the deep veins to the superficial veins, and (2) all branch varicosities must be removed. Reflux must be eliminated from all major problem areas, including the saphenofemoral junction, the saphenopopliteal junction, and the mid thigh Hunterian perforator vein. To identify these problem areas, careful preoperative duplex mapping of major superficial venous reflux is essential. All varicose vein clusters are meticulously marked before operation; they may be difficult to identify during the procedure, when the patient is supine.

At present, three techniques are approved for the elimination of axial reflux in the GSV and the SSV: (1) traditional surgical stripping, (2) laser vein ablation (i.e., endovenous laser therapy [EVL]), and (3) radiofrequency (RF) ablation. Regardless of which technique is employed, the principal goals of treatment (see above) are the same. In addition, the procedure must be done in a manner that optimizes cosmetic results and minimizes complications.

Endovenous Procedures

Current endovenous techniques for treating varicose veins are based on three major developments: (1) the availability of laser and RF probes that deliver heat endovenously, (2) the introduction of tumescent anesthesia, and (3) the evolution of duplex ultrasonography. Tumescent anesthesia allows physicians to use large volumes (500 ml) of dilute (0.1%) lidocaine in a single session while achieving anesthesia levels equivalent to those achieved with 1% lidocaine. In this way, the entire thigh portion of the GSV can be safely anes-

thetized (and consequently obliterated) at one time. Epinephrine can be added to the solution to improve postoperative hemostasis, increase venous contraction around the heat-generating catheter, and lengthen the duration of postprocedural analgesia. A common formula for the tumescent anesthesia solution is 450 ml of normal saline mixed with 50 ml of 1% lidocaine with epinephrine (1:100,000 dilution) and 10 ml of sodium bicarbonate to buffer the acidity of the lidocaine.

Duplex ultrasonography has revolutionized treatment of varicose veins. It dramatically enhances physicians' ability to evaluate the cause of varicosities and to tailor treatment so that only the diseased vein segments are ablated while the normal segments are preserved. It also serves to guide placement of sheaths and heat-generating catheter tips, allowing these devices to be situated very precisely within the vein.

TECHNIQUE

Laser Vein Ablation

Laser vein ablation [see Figure 2] may be performed either in the office or in the hospital. Reimbursement issues make in-office treatment advantageous for most physicians. Neither conscious sedation nor noninvasive monitoring is required. On occasion, a nervous patient may benefit from administration of an oral anxiolytic agent 1 to 2 hours before the procedure.

Standard surgical preparation and draping are indicated, including the use of sterile gowns, masks, drapes and aseptic technique. Depending on the results of the preoperative physical examination and duplex ultrasonography, the GSV, the SSV, the anterior accessory saphenous vein, or the posterior accessory saphenous vein may be treated, either alone or in combination with other vessels as necessary. The GSV is usually treated from the upper third of the calf to the saphenofemoral junction. If the calf portion of the GSV is to be treated, tumescent anesthesia should be liberally employed to reduce the risk of saphenous nerve injury. The SSV is treated from the distal third of the calf to the point where it angles toward the popliteal vein in the popliteal fossa. The relation of the sural nerve to the distal third of the SSV precludes safe treatment of this portion of the vein, and the proximity of the popliteal nerve to the SSV in the popliteal fossa precludes safe treatment of the most proximal portion of the vein. The procedure does not allow flush ligation of the saphenofemoral junction, but current evidence suggests that this measure may not be indicated: flush ligation eliminates normal venous drainage from the saphenofemoral junction and may increase the risk of neovascularization of the saphenofemoral junction and recurrence of varicosities.

The saphenous vein being treated is accessed with a micropuncture system after a small amount of lidocaine (sufficient to raise a small skin wheal) is injected into the dermis. The position of the 0.015-in. wire in the saphenous vein is confirmed by means of ultrasonography. A 4 French catheter is then passed over the wire, allowing the placement of a 0.035-in. wire for access to the proximal portion of the saphenous vein. Next, the 0.035-in. wire is positioned at the appropriate saphenous junction, and a 5 French vascular sheath is advanced over the wire to the junction. The sheath is positioned either just below the superior epigastric vein or 1 to 2 cm distal to the junction of the GSV; if the SSV is being treated, the tip is positioned 2 to 3 cm below the junction at the point where the vein makes its transition from an oblique course to a parallel path under the fascia of the leg. The 600 μ m laser fiber is then passed to the tip of the sheath, which is pinned and pulled to expose the tip of the laser fiber. The rigidity and sharpness of the laser fiber makes advancing its tip dangerous. Most laser systems allow the fiber to be locked to the sheath, so that the

Figure 1 Shown is an ultrasonographic image of the so-called saphenous eye. Correct identification of this marker is crucial to correct performance of the preoperative ultrasonographic reflux examination.

Figure 2 Ablation of great saphenous vein. Shown is percutaneous placement of a quartz fiber for laser ablation of the GSV. In practice, the catheter used for RF ablation is placed in a similar fashion. Both laser ablation and RF ablation deliver electromagnetic energy to the vein wall to destroy the vessel and remove it from the circulation.

two devices can be advanced and positioned as a single unit.

To this point in the procedure, no anesthesia other than the initial dermal injection has been employed. The next step, accordingly, is to initiate tumescent anesthesia, with or without epinephrine, along the saphenous compartment. The addition of epinephrine to the anesthetic solution results in improved constriction of the vein around the laser sheath, particularly when a saphenous vein larger than 12 mm in diameter is being treated; it also prolongs the analgesic effect of lidocaine, providing pain relief for as long as 6 to 8 hours after the procedure. A particular benefit of tumescent anesthesia is that the large volume of the injectate constitutes a heat sink that absorbs the heat created by the laser, thereby eliminating injury to surrounding soft tissue structures (e.g., nerves, fat, and skin). Further protection against injury is provided by rapid pullback of the laser fiber. As a result, the reported incidence of thermal skin or nerve injuries with laser vein ablation is almost zero.

Administration of the tumescent anesthesia solution starts at the sheath entry site and continues proximally until the entire vein segment to be treated exhibits a circumferential zone of echolucence. The vein is generally treated in the saphenous compartment between the superficial and deep fasciae of the leg. The anesthetic is administered via a 22-gauge needle with a 20 ml syringe or, alternatively, via a 10 ml autofill syringe or a Klein pump (both of which have the advantage of allowing more rapid administration with less risk of needle-stick injury to the staff). The needle is kept in a static position during administration, and the fluid is allowed to dissect up and down the fascial compartment.

Besides providing pain relief, tumescent anesthesia serves to move the saphenous vein being treated away from any structure that might be injured by the heat produced by the laser (e.g., the skin and the femoral vein). A 1 cm distance between the skin and the laser fiber is optimal. More liberal amounts of tumescent anesthesia

solution are administered when the vein being treated lies in close proximity to one or more nerves (e.g., the SSV and the calf portion of the GSV). As a rule, we prefer not to treat the subdermal portions of the GSV with laser ablation; the presence of an inflamed and tender vein just beneath the dermis is likely to lead to increased postoperative pain and noticeable skin discoloration. The superficial segments of the GSV are best treated with phlebectomy at the time of laser ablation.

When administration of the tumescent anesthesia solution is complete, the position of the laser fiber's tip is again confirmed. As the vein constricts, it also shortens, and this process may advance the tip of the laser fiber into the saphenofemoral or saphenopopliteal junction. If the tip is found to have moved in this manner, it is withdrawn until it is again 1 to 2 cm below the junction. A quick scan down the vein is done to confirm that the entire vein is surrounded by the anesthetic solution and is at least 1 cm from the skin.

At this point, the laser may be safely activated. The laser is always used in the continuous mode. The power setting may range from 10 to 12 W, depending on the physician's personal preference. We typically employ a 10 W setting for veins smaller than 10 mm and a 12 W setting for veins larger than 10 mm. The essential point is that between 50 and 100 J must be delivered to each centimeter of vein treated; according to one study, 70 J/cm is the ideal amount for reliable long-term vein obliteration.⁵ Energy delivery can easily be determined as the laser fiber is withdrawn. Most laser sheaths have markings 1 cm apart, and the laser machines have digital readouts that indicate the total amount of energy (J) delivered in real time. A simple calculation after 10 cm of the catheter has been withdrawn provides instant feedback on the energy delivered per centimeter of vein. On the 12 W power setting, delivery of the recommended amount of energy generally necessitates a pullback rate of 1 cm every 4 to 5 seconds (2.0 to 2.5 mm/sec). One group has advocated

delivery of 140 J/cm proximally (pullback rate of 1 mm/sec) and roughly 70 J/cm distally (pullback rate of 3 mm/sec), theorizing that for long-term success, more energy is required proximally.⁶ At the completion of the procedure, the laser is deactivated before the fiber is withdrawn from the skin. Ultrasonography is then performed to confirm that the common femoral vein and the superficial epigastric vein are patent and that the GSV is occluded.

An adhesive strip (e.g., Steri-Strip; 3M, St. Paul, Minnesota) covered by a transparent surgical adhesive dressing is applied over the entry site. The patient is then placed in a prescription compression stocking, which is worn for 1 to 2 weeks after the procedure. Whereas most physicians use a class 2 (30 to 40 mm Hg) compression stocking, we have switched to using a class 1 (20 to 30 mm Hg) stocking without observing any changes in complications (e.g., postoperative pain and swelling) or results. This switch has enhanced patient satisfaction, in that a class 1 stocking is easier to don and more comfortable to wear.

A 2003 study that followed 499 limbs over 2 years demonstrated a varicosity recurrence rate of less than 7% after ablation of the GSV with an 810 nm diode laser.⁷ This rate is comparable to or lower than those reported after traditional surgical stripping, RF ablation, and ultrasound-guided sclerotherapy. Several smaller studies documented similar outcomes, making it evident that laser vein ablation is both effective and safe when compared to other means of treating varicose veins [see Table 3].^{1,6,8-11}

At present, the question of how to manage residual varicosities after laser ablation remains controversial. The two main options are (1) to perform phlebectomy simultaneously with laser vein ablation and (2) to perform laser ablation alone, then observe the patient for spontaneous regression of varicosities. When the residual varicosities are left untreated, 10% to 20% of patients show sufficient regression to render further intervention unnecessary; however, 5% to 10% of patients experience superficial thrombophlebitis in the residual varicosities as a consequence of stasis from altered venous drainage. If delayed treatment of residual varicosities proves necessary, it may be accomplished with either phlebectomy or sclerotherapy, depending on the physician's preference. Our treatment of choice is laser vein ablation with concurrent phlebectomy. This approach adds only 10 to 20 minutes to the length of the procedure while offering the patient a more rapid and complete resolution of visible varicose veins and greatly reducing the risk of secondary thrombophlebitis.

Radiofrequency Ablation

In an attempt to minimize postoperative discomfort while main-

taining the benefits of saphenous vein ablation, RF alternating current has been employed to effect rapid thermic electrocoagulation of the vein wall and its valves. This approach is exemplified by the Closure procedure (VNUS Medical Technologies, Inc., San Jose, California). Prolonged exposure to the high-frequency energy results in total loss of vessel wall architecture, disintegration, and carbonization.¹² Ultrasonographic follow-up shows that treated saphenous veins disappear after the 2-year point. Clinical observations suggest that patients are much more comfortable after RF ablation than after surgical stripping.¹³

The technique of RF ablation is somewhat similar to that of laser ablation [see Figure 2] but differs in several important respects [see Laser Vein Ablation, above]. After percutaneous access is obtained, either a 6 or an 8 French RF radiofrequency catheter is placed 1 to 2 cm from the saphenofemoral junction, and tumescent anesthesia is instituted. The probe is connected to the RF generator box, the tines of the probe are exposed, and the unit is activated. The catheter is pulled back slowly (1 cm every 30 seconds) while its temperature and impedance are monitored. In the procedure as originally performed, the catheter was heated to 85° C, but current approaches often involve heating the catheter to 90° or 95° C with the aim of shortening the pullback time (to compete with the shorter pullback times characteristic of laser ablation). In general, however, pullback times are still somewhat longer with RF ablation than with laser ablation, allowing more dissemination of heat to surrounding tissue; postprocedural paresthesia continues to be reported in about 12% of cases.¹⁴ The technical results of RF ablation are excellent: with the Closure procedure, the closure rate at 4 years is 89%.¹⁴ However, the continued occurrence of paresthesias and the slower pullback times associated with RF ablation still appear to make laser vein ablation a safer and more rapid procedure.

The issue of recurrent varicosities after obliteration of the GSV without disconnection of the saphenofemoral junction tributaries is unsettled at present. It does appear, however, that endovenous RF ablation of the GSV (e.g., with the Closure procedure) prevents subsequent neovascularization in the groin. Many centers have reported that neovascularization does not occur in the absence of a groin incision.

The specific goal of endoluminal treatment of venous reflux is obliteration of the saphenous vein. Follow-up to 4 years shows that RF ablation with the Closure procedure accomplishes this goal.¹⁴

OUTCOMES AND COMPLICATIONS

Both EVLT and RF ablation have proved to be effective and safe

Table 3 Complications of Laser Vein Ablation and Radiofrequency (RF) Ablation in Selected Studies¹⁵

Ablation Method	Study	Limbs Treated (N)	Skin Burn (%)	Paresthesia (%)	Phlebitis (%)	DVT (%)	Recanalization (%)

Figure 3 Shown are a typical saphenofemoral junction and the most important tributary vessels. The classic surgical approach dictates total disconnection of all tributaries at this junction.

for the treatment of venous reflux disease. Several studies that followed treated limbs for 2 years or longer have shown that with respect to efficacy, these modalities are equivalent or superior to standard surgical techniques.^{7,11,15,16} It is noteworthy that neovascularization seems to be almost nonexistent with endovenous procedures; this result appears to be related exclusively to standard ligation surgery.

Multiple studies have reported similar end-point results for EVLT and RF ablation: long-term occlusion of the GSV is consistently achieved at rates approaching or exceeding 90%. In general, EVLT has somewhat better long-term success rates, ranging from 92% to 95%; RF ablation generally yields success rates between 85% and 91%. The incidence of DVT (which is more accurately described as extension of thrombus from the treated vein into the deep venous system) is low with both procedures but is slightly higher with RF ablation. No cases of life-threatening pulmonary embolism have been reported with either EVLT or RF ablation, and both are associated with only negligible rates of superficial thrombophlebitis, cellulitis, (excessive) pain, and transient paresthesias.

A 2006 study stressed the importance of treating the posterior thigh circumflex vein so as to lower the incidence of recanalization.¹⁵ A large posterior thigh circumflex vein can drain cool blood into the segment being ablated, thus inhibiting proper heating of the refluxing segment and making adequate closure more difficult. Accordingly, the authors recommended ablating any posterior thigh circumflex veins larger 4 mm in tandem with the primary procedure.

Surgical Vein Stripping

Ligation of the GSV at the saphenofemoral junction [see Figure 3] has been widely practiced in the belief that it would control gravitational reflux while preserving the vein for subsequent arterial bypass.

It is true that the GSV is largely preserved after proximal ligation¹⁷; however, reflux continues, and hydrostatic forces are not controlled.¹⁸ Recurrent varicose veins are more frequent after saphenous ligation than after stripping.¹⁹ Varicosities also recur more frequently after ligation and sclerotherapy than after stripping and sclerotherapy.²⁰ A prospective, randomized trial that compared proximal GSV ligation and stab avulsion of varices with stripping of the thigh portion of the GSV and stab avulsion of varices showed the latter approach to be superior.^{21,22} Routine GSV stripping reduces the rate of recurrent varicosities and the need for reoperation for recurrent saphenofemoral incompetence.

Although it can be argued that the GSV should be retained for possible use in arterial bypass grafting, the relatively high (> 20%) reoperation rate makes this strategy undesirable. Almost three quarters of limbs that undergo GSV ligation alone have an incompetent GSV on follow-up duplex imaging. Until studies show a clear advantage to retaining the GSV in defined patient populations, surgical stripping should remain a routine part of primary GSV surgery. In several studies, preservation of the patency of the GSV and continuing reflux in this vein were found to be the factors most frequently associated with recurrence of varicosities.²³⁻²⁵ In one study of patients who underwent reoperation for relief of recurrent variceal symptoms, two thirds of the patients required removal of the GSV as part of the procedure.²³

Over the past 100 years, ankle-to-groin stripping of the GSV has been the dominant approach to treatment of varicose veins.²⁶⁻²⁸ It has been argued, however, that routine stripping of the leg (i.e., ankle-to-knee) portion of the GSV is inadvisable. One argument against this practice is that there is a significant risk of concomitant saphenous nerve injury [see Figure 4].¹⁹ Another argument is that whereas the objective of GSV removal is detachment of perforating veins emanating from the GSV in the thigh, the perforating veins in the leg are actually part of the posterior arch vein system rather than of the saphenous vein system. This latter argument notwithstanding, preoperative ultrasonography often demonstrates that the leg portion of the GSV is in fact directly connected to perforating veins. It is clear, however, that elimination of the refluxing thigh portion of the GSV frequently eliminates reflux in the calf portion of the vein, even when the calf portion is left behind. Therefore, removal of the GSV from ankle to knee generally is not necessary. If reflux subsequently becomes a problem in this portion of the vein, it can usually be controlled with sclerotherapy.

OPERATIVE TECHNIQUE

The surgical approach to vein stripping must be tailored to the individual patient and the individual limb being treated. As a rule, general or spinal anesthesia is required, though the procedure can also be performed with tumescent anesthesia. Groin-to-knee stripping of the GSV should be considered in every patient requiring surgical intervention.²⁹ In nearly all patients, this measure is supplemented by removal of the varicose vein clusters via stab avulsion or some form of sclerotherapy [see Table 4].

Step 1: Placement of Incisions

Preoperative marking, if correctly performed, will have documented the extent of varicose vein clusters and identified the clinical points where control of varices is required. Incisions can then be planned. As a rule, incisions in the groin and at the ankle should be transverse and should be placed within skin lines. In the groin, an oblique variation of the transverse incision may be appropriate. This incision should be placed high enough to permit identification of the saphenofemoral junction [see Figure 3]. The use of a portable ultrasound unit in the operating room facilitates placement of the inci-

sion directly over the saphenofemoral junction. Generally, throughout the leg and the thigh, the best cosmetic results are obtained with vertical incisions. Transverse incisions are used in the region of the knee, and oblique incisions are appropriate over the patella when the incisions are placed in skin lines.

A major cause of discomfort and occasional permanent skin pigmentation is subcutaneous extravasation of blood during and after saphenous vein stripping. Such extravasation can be minimized by using tumescent anesthesia around the vein to be stripped.

The practice of identifying and carefully dividing each of the tributaries to the saphenofemoral junction has been dominant over the past 50 years. The rationale for this practice is to avoid leaving behind a network of interanastomosing inguinal tributaries. Accordingly, special efforts have been made to draw each of the saphenous tributaries into the groin incision so that when they are placed on traction, their primary and even secondary tributaries can be controlled. The importance of these efforts has been underscored by de-

Figure 4 Surgical stripping of great saphenous vein. Illustrated is an early attempt to minimize distal incisions and prevent saphenous nerve injury at the knee. The stripper and its obturator are pulled to knee level, then retrieved through the groin incision. (Note division of perforating and communicating veins.)

Table 4 Methods of Variceal Ablation

scriptions of residual inguinal networks as an important cause of varicose vein recurrence.²³ Currently, however, this central principle of varicose vein surgery is under challenge, on the grounds that groin dissection can lead to neovascularization and hence to recurrence of varicosities [see Outcome Evaluation, below].

Step 2: Introduction of Stripping Device

Preoperative duplex studies having already demonstrated incompetent valves in the saphenous system, a disposable plastic Codman stripper can be introduced from above downward; alternatively, an Oesch stripper can be employed.³⁰ Both of these devices can be used to strip the GSV from groin to knee via the inversion technique [see Figure 5]. This approach has been shown to reduce soft tissue trauma in the thigh.³¹

In the groin, the stripper is inserted proximally into the upper end of the divided internal saphenous vein and passed down the main channel through incompetent valves until it can be felt lying distally approximately 1 cm medial to the medial border of the tibia at a point approximately 4 to 6 cm distal to the level of the tibial tubercle. The GSV is anatomically constant in this location, just as it is in the groin and ankle. If the GSV is removed from the groin to this level, both the midthigh perforating vein, which usually enters the GSV, and the most distal incompetent perforating veins, which are in the distal third of the thigh, will be treated.

A small incision is made over the palpable distal end of the stripper. The GSV will subsequently be divided through this incision, and the stripper and the inverted vein will be delivered through it. In exposing the GSV at knee level, the superficial fascia must be incised because the vein lies between this structure and the deep fascia of the thigh.

If the stripper passes unimpeded to the ankle, it can be exposed there with an exceedingly small skin incision placed in a carefully chosen skin line. Passage of the stripper from above downward to the ankle serves to confirm the absence of functioning valves, and stripping of the vein from above downward is unlikely to cause nerve damage. At the ankle, the vein should be carefully and cleanly dissected to free it from surrounding nerve fibers. If this is not done, saphenous nerve injury will result, and the patient will experience numbness of the foot below the ankle.

Step 3: Removal of Saphenous Vein

The previously placed stripper is pulled distally to remove the GSV. Although plastic disposable vein strippers and their metallic equivalents were designed to be used with various-sized olives to remove the GSV, in fact, a more efficient technique is simply to tie the vein to the stripper below its tip so that the vessel can then be inverted into itself and removed distally, usually at knee level.

Phlebectomy for Management of Residual Varicosities

Management of residual varicose veins after vein stripping traditionally has been done at the same time as the surgical procedure.

Figure 5 Surgical stripping of great saphenous vein. Inversion stripping of the GSV decreases soft tissue trauma in the thigh. However, tearing of the vein occurs on occasion. This problem may be largely prevented by attaching a corner of a 2 in. gauze roll soaked in lidocaine-epinephrine solution to the end of the stripper. As the stripper is pulled, the gauze is drawn into the vein, thereby assisting hemostasis. The gauze can then be left in place for 10 to 20 minutes while the stab wounds from the avulsion part of the procedure are being closed.

Management of residual varicose veins after vein ablation is more controversial. Currently, many physicians who treat vein disease are not familiar with the surgical technique of phlebectomy and therefore elect to wait for varicosities to regress after vein ablation. In 10% to 20% of cases, enough regression of varicose veins occurs after ablation that no further treatment is required. If delayed treatment proves necessary, it may be accomplished by means of either phlebectomy or sclerotherapy, depending on the physician's preference.

The technique of phlebectomy is easy to learn. A tumescent anesthesia solution is infused between the skin and the superficial fascia of the leg in the area of the previously marked varicosities. The infusion of the anesthetic tends to dissect the GSV away from the surrounding tissue and causes vasoconstriction. Vertical incisions 1 to 3 mm in length are made where appropriate. In the anterior knee and ankle regions, where skin lines are obviously horizontal, incisions are hidden in the lines [see Figure 6]. Varicosities are exteriorized by means of hooks or forceps; particularly useful for this purpose are specially designed vein hooks such as the Varady dissector, the Muller hook, and the Oesch hook [see Figures 7 and 8].³² Nothing should penetrate the skin other than the small end of the hook. Usually, the vein is easily distinguished from the surrounding fat by its taut rubber band feel. The vessel is brought out of the skin, then removed proximally and distally by using a hand-over-hand technique with mosquito clamps. Eventually, the vein tears in each direction, but because of the epinephrine in the tumescent anesthesia solution, very little bleeding occurs. The procedure is continued in a proximal-to-distal direction until all varicose clusters have been removed; generally, between 10 and 15 incisions are required for removal of all clusters. Veins of any size can be removed by means of this technique, even in the office setting. In patients who have had superficial phlebitis or have previously undergone sclerotherapy, the veins typically are fibrotic and adherent to the surrounding tissue and cannot be easily removed. If treatment of such veins proves necessary at some point in the future, sclerotherapy is generally the method of choice.

When all phlebectomies have been completed, small elastic strips are used to close the skin incisions. A compressive dressing is applied for 24 hours to minimize bleeding, bruising, and swelling. When the procedure is done properly, the incisions are invisible by 6 to 8 weeks and the patients are very happy with the results. Experienced workers in Europe have achieved marked refinements of phlebectomy techniques for varicose clusters.³³

COMPLICATIONS

Surgical removal of the GSV on an outpatient basis still requires two incisions, one in the groin and the other near the knee. Postoper-

Figure 6 Surgical stripping of great saphenous vein: phlebectomy for residual varicosities. (a) Skin incisions for stab avulsion of varicosities are limited with respect to both length and depth. (b) The dissector blade facilitates mobilization of the vein before removal.

Figure 7 Surgical stripping of great saphenous vein: phlebectomy for residual varicosities. Shown are tools used for exteriorizing varicosities: a Hartman clamp with its single tooth placed distally, two Muller clamps, and a Varady hook and dissector (left to right).

ative compression bandaging is standard, and most patients experience little downtime. Some, however, do experience hematoma, pain, and extensive bruising. These three complications are linked; thus, every effort should be made to prevent oozing. The most feared complication of varicose vein surgery is venous thromboembolism, but the incidence of this complication is quite low (probably about 1%). In countries where postoperative immobilization, hospitalization, and delayed ambulation are employed for patients with varicosities, prophylaxis against venous thromboembolism is common. In the United States, however, this measure is generally considered unnecessary in these patients. The most common complication of varicose vein surgery is recurrence of varicosities, which is experienced by 15% to 30% of patients treated.²⁴

To speak of permanent removal of varicosities implies that all potential causes of recurrence have been considered and that surgical management has been planned so as to address them. There are four principal causes of recurrence of varicose veins, three of which can be dealt with at the time of the primary operation.

One cause of recurrent varicosities is failure to perform the primary operation correctly. Common errors include missing a duplicated saphenous vein and mistaking an anterolateral or accessory saphenous vein for the GSV. Careful and thorough anatomic identification will help minimize such errors. It has long been held that a second cause of recurrent varicose veins is failure to do a proper groin dissection; however, it is now known that such dissection causes neovascularization in the groin, leading to recurrence of varicose veins [see Outcome Evaluation, below]. A third cause is failure to remove the GSV from the circulation. A reason often cited for this failure is the desire to preserve the GSV for subsequent use as an arterial bypass, but it is clear that the preserved GSV continues to reflux and continues to elongate and dilate its tributaries, thereby producing more varicosities even after primary operative treatment has removed the varicose veins present at the time. A fourth cause of recurrent varicosities is persistence of venous hypertension through nonsaphenous sources—chiefly perforating veins with incompetent valves. Muscular contraction generates enormous pressures that are directed against valves in perforating veins. Venous hypertension induces a leukocyte endothelial reaction, which, in turn, incites an inflammatory response that ultimately destroys the venous valves and weakens the venous wall.³⁴ The perforating veins most commonly associated with recurrent varicosities are the midthigh perforating vein, the distal thigh perforating vein, the proximal anteromedial calf perforating vein, and the lateral thigh perforating vein, which connects the deep femoral vein to surface varicosities.

In addition to the four principal causes of recurrent varicosities, there is a fifth cause, which is beyond the operating surgeon's control—namely, the genetic tendency to form varicosities. This tendency results in the development of localized or generalized venous wall weakness, localized blowouts of venous walls, or stretched, elongated, and floppy venous valves.^{35,36}

OUTCOME EVALUATION

As a rule, when undesirable outcomes occur after surgical saphenous vein stripping, they become evident quite early.²¹ As noted (see above), it has long been accepted practice to dissect tributary vessels at the saphenofemoral junction very carefully, taking each of the vessels back beyond the primary and even the secondary tributaries if possible.³¹ In practice, however, such dissection appears to cause neovascularization in the groin³⁷; surveillance with duplex ultrasonography supports this finding.³⁸ It has now been amply confirmed that neovascularization causes recurrent varicose veins. Clearly, this is a significant disadvantage of standard surgical treatment of varicosities. This disadvantage has been a major impetus for the development of less invasive alternatives to surgical saphenous vein stripping [see Endovenous Procedures, above, and Foam Sclerotherapy, below]. These alternatives are proving to be effective and may be superior to surgical stripping, if only because they are not followed by groin neovascularization.

Foam Sclerotherapy

The prospect of a rapid, minimally invasive, and durable treatment of varicose veins is an attractive one. Current evidence suggests that these objectives may be achieved without operative intervention by using sclerosant microfoam [see Figure 9]. In 1944 and 1950, E. J. Orbach introduced the concept of a macrobubble air-block technique to enhance the properties of sclerosants in performing macrosclerotherapy.^{39,40} At the time, few clinicians evinced much interest in the subject, and the technique languished.

Figure 8 Surgical stripping of great saphenous vein: phlebectomy for residual varicosities. The varix is exteriorized with a hook, then divided to permit proximal and distal avulsion.

Figure 9 Microfoam sclerotherapy. (a) The relationships among the venous structures in a lower extremity with varicosities explain why microfoam sclerotherapy can succeed. Injections into varices, reticular veins, or perforating veins can place the foam into varicose structures and even into telangiectatic blemishes. (b) Sclerosant foam is made by mixing room air with 0.5% sodium tetradecyl sulfate (STS) in a 2:1 ratio via a three-way stopcock. The syringes are emptied 35 times to create a foam that lasts about 5 minutes. (c) A halogen light (vein light), as used here during a foam injection, is helpful for treating persistent or recurrent varices along with the GSV in situations where surgery is undesirable.

Half a century later, the work of Juan Cabrera and colleagues in Granada attracted the attention of some phlebologists and reawakened interest in using foam technology for the treatment of venous insufficiency.⁴¹ These investigators showed that foam sclerotherapy was technically simple and worked well in small to moderate-sized varicose veins, and they demonstrated that the limitations of liquid sclerotherapy could be erased by using microfoam. Their 5-year report represents the longest observation period to date for microfoam sclerotherapy for varicose veins. In most of the cases, a single injection sufficed to treat saphenous veins and varicose tributaries. Extensive vasospasm was seen immediately, but compression was applied after treatment. Complete fibrosis of the saphenous vein was achieved in 81% of cases, and patency with reflux persisted in only 14%. Tributary varicosities disappeared in 96% of cases. Vessels that remained open and were refluxing were successfully closed with retreatment.

A subsequent study demonstrated that even severely affected

limbs could be safely and effectively treated by means of foam sclerotherapy combined with compression.⁴² In this study, limbs affected by lipodermatosclerosis, atrophie blanche, or even open venous ulcers showed statistically significant improvement after the injection of a foamed sclerosant followed by compression with a medical-grade stocking or an Unna boot. The study results also underscored the importance of applying compression immediately after the injection of the sclerosant. Limbs that underwent foam sclerotherapy and compression healed better and more quickly than limbs that were treated by sclerotherapy alone.

If subsequent work continues to confirm these favorable results, it may be that microfoam sclerotherapy will eventually replace all other methods of varicose vein treatment. As of December 2006, however, foam sclerotherapy had not been approved by the United States Food and Drug Administration, because of concerns about potential air embolization after the injection of the sclerosant.

19 ENDOVASCULAR PROCEDURES FOR LOWER-EXTREMITY DISEASE

Heather Y. Wolford, M.D., and Mark G. Davies, M.D., Ph.D., F.A.C.S.

Endovascular procedures are increasingly being applied to the treatment of lower-extremity vascular disease: for many common vascular conditions, minimally invasive approaches have become important supplements to (or even supplanted) conventional open surgical approaches.¹ The evolution of these endovascular techniques is likely to result in a corresponding evolution in the therapeutic decision-making process for patients with lower-extremity vascular disease. Research into the long-term outcomes of lower-extremity endovascular procedures will be necessary for a better understanding of the indications for treatment and of the risks and benefits for patients.

Arterial Procedures

Arterial conditions of the lower extremity that may be treated with endoluminal therapy include chronic ischemia, acute ischemia, and aneurysmal disease. The fundamental skill set and the basic techniques employed are the same for all of these conditions. Accordingly, the ensuing discussion first reviews the basics of endovascular therapy and then focuses on specific areas of chronic, acute, and aneurysmal arterial disease of the lower extremity that are amenable to endoluminal intervention.

BASIC ENDOVASCULAR PROCEDURES

Preprocedural Evaluation

Clinical evaluation The first step in the intervention consists of a thorough history and a careful physical examination. Patients should be specifically asked about chronic renal insufficiency, current or past anticoagulant therapy, and previous vascular and endovascular interventions. Lower-extremity pulses should be assessed, and the degree of ischemia present should be determined [see Table 1]. Basic serum biochemical and hematologic data should be obtained and reviewed. The results of any previous imaging studies should also be obtained and reviewed. Patients with serum creatinine concentrations higher than 1.5 mg/dl should be considered for a renal protection protocol [see Table 2], and at the time of the procedure, the use of an alternative contrast

agent to decrease total nephrotoxic dye volumes (see below) may be considered. Patients taking oral hypoglycemic agents are asked to stop doing so on the day of the procedure and not to resume for 48 hours after the procedure. In general, to prevent bleeding complications, it is preferred that the international normalized ratio (INR) be lower than 1.6 and the platelet count higher than 50,000/mm³ at the time of intervention.

If a therapeutic intervention is planned, the patient should be given aspirin, 81 mg/day, and clopidogrel, 75 mg/day, for at least 3 days beforehand. If there is not enough time to do this, the patient may be given clopidogrel, 150 to 300 mg, within the 2 hours preceding the procedure.

Investigative studies Imaging is required before any intervention. Noninvasive vascular ultrasonographic studies document the initial status of the arterial blood supply and allow localization of the culprit lesions. The ankle-brachial index (ABI) (or, in diabetics and patients with incompressible ankle vessels, the toe-brachial index), pulse-volume recordings (PVRs), and segmental pressures quantify arterial perfusion and define areas of stenosis or occlusion within each leg. Duplex ultrasonography is an alternative to PVRs and segmental pressures and provides further diagnostic information that allows the interventionalist to identify involved vessel segments and lesions amenable to percutaneous therapy. These objective measurements serve as a baseline against which postinterventional results may be assessed.

Generally, noninvasive studies provide sufficient information to allow one to proceed with diagnostic angiography and possible endoluminal intervention. In many cases, however, additional studies are required to refine the interventional plan and to reduce the time and resources required. Computed tomographic angiography (CTA) provides two-dimensional images of the arterial system, which are then postprocessed to generate three-dimensional reconstructions. It is particularly effective for imaging tibial vessels. The main drawbacks of CTA are the time necessary to reconstruct the images, the possibility of interference from metal implants, and the contrast load involved. Magnetic resonance angiography (MRA) also provides potentially helpful preprocedural

<i>N</i> -acetylcysteine, 600 mg p.o., b.i.d., for total of four doses; first dose given 12 hr before procedure Theophylline, 200 mg I.V., given 30 min before procedure, or 200 mg p.o., b.i.d., starting 24 hr before procedure and continued for 48 hr after procedure	Hydration with normal saline, starting 1 hr before procedure and continued for 3 hr after procedure Sodium bicarbonate drip, 154 mEq/L, starting 1 hr before procedure and continued for 6 hr after procedure Use of alternative contrast agent

information and has the advantage of using gadolinium, which is a relatively low risk contrast agent for patients with renal insufficiency. The main drawbacks of MRA are relatively poor patient tolerance of the machine, the tendency to overestimate lesion severity, the long image acquisition time, and the variability in image quality as one proceeds distally in the leg. Patients with limited arterial access will benefit from a cross-sectional imaging algorithm: such an approach allows one to perform a focused angiogram and to make more efficient use of resources during a therapeutic intervention.

Preprocedural Planning

Choice of arterial access site The common femoral artery (CFA) contralateral to the affected side is the arterial access site most commonly employed. If the patient has an occluded CFA or a “hostile groin,” a radial, high brachial, or axillary artery approach may be chosen instead; however, access at these sites is associated with a relatively higher incidence of complications. Ideally, to facilitate manual compression, the access site should lie over a flat bony prominence. An antegrade ipsilateral CFA approach is a useful alternative to contralateral access if there is a contraindication to working from the contralateral side (e.g., significant contralateral iliac disease, a heavily scarred groin, recent application of a vascular closure device, or a bifurcated aortic graft) and if preoperative imaging has demonstrated that there is an adequate working distance (generally, at least 15 to 20 cm) between the CFA access point and the target lesion. If an antegrade approach fails, a retrograde approach may be employed to target ipsilateral iliac arterial disease from the CFA or superficial femoral artery (SFA) disease from the popliteal artery.

Selective Lower-Extremity Angiography

Technique Standard methods of obtaining vascular access for angiography are described in more detail elsewhere [see 6:8 *Fundamentals of Endovascular Surgery*]. For selective angiography of the lower extremity, a 4 or 5 French diagnostic sheath is initially placed in the CFA contralateral to the affected extremity. A 4 or

5 French multi-side-hole diagnostic catheter (in a straight, curved, or pigtail configuration) is then placed over a wire into the juxtarenal aorta. After the initial aortic films are obtained in the anteroposterior (AP) projection, the diagnostic catheter is moved down to a point 2 to 3 cm above the aortic bifurcation, and a series of pelvic images are taken in the AP and lateral projections.

The aortic bifurcation is generally traversed with a curved catheter; the curve of the tip should be similar to the angle of the bifurcation. A wire is maneuvered into the iliac system and positioned in the external iliac artery or the CFA, and the curved diagnostic catheter is advanced to the point where its tip lies within the distal external iliac artery and its holes are beyond the ostium of the internal iliac artery.

Once the catheter has been correctly positioned, further contrast injections are performed. Complete lower-extremity images, which should include tibial and pedal vessels (in AP and magnified lateral foot views), are taken before the intervention so that preprocedural status can be compared with postprocedural status and any distal complications can be recognized. Contrast doses commonly employed for digital subtraction arteriography (DSA) depend on the specific arterial segment being addressed [see Table 3].

Alternative contrast agents. Standard angiography is performed with an iodinated nonionic contrast agent. In patients with creatinine concentrations higher than 1.5 mg/dl, an alternative contrast agent may be preferable. Carbon dioxide may be used to image the abdominal aorta, the iliac arteries, and, occasionally, the proximal leg arteries. As the vessels become smaller, however, CO₂ images become less clear. Elevating the legs may help in obtaining adequate imaging to the level of the knees. For CO₂ imaging, a 60 ml syringe is connected to a three-way stopcock, and CO₂ from a tank is loaded into the syringe through the stopcock assembly while the stopcock is submerged in normal saline and manually kept under pressure. The submerged system is flushed with CO₂ several times to purge any residual air. The CO₂-containing syringe is connected to an indwelling catheter, and the CO₂ is then injected forcefully by hand while the fluoroscopy unit is activated. The resulting images must undergo postprocessing to be viewed correctly. CO₂ imaging should not be used above the diaphragm or in the visceral artery segment of the aorta.

Gadolinium may also be used to image the pelvic vessels and the proximal leg arteries. Like CO₂ images, gadolinium images become less clear as the lower-extremity arteries become smaller and more distal. Gadolinium is loaded into the power injector or injected by hand, like standard contrast agents. Doses higher than 0.3 mmol/kg may be nephrotoxic.²

Troubleshooting If crossing the aortic bifurcation proves difficult, changing to a hydrophilic wire (e.g., a 0.035-in. soft or

Table 3 DSA Imaging Techniques with Power Injector

Arterial Segment Imaged	View	Contrast Dosage	Delay
Infrarenal aorta	AP	10–20 ml/sec for 2 sec	No
Iliac arteries	AP/oblique	3–10 ml/sec for 2–3 sec	No
CFA and SFA	AP	3–10 ml/sec for 2–3 sec	Flow dependent
Tibial arteries	AP	3–5 ml/sec for 3–4 sec	Yes
Pedal artery	AP/lateral foot	3–6 ml/sec for 3–4 sec	Yes

AP—anteroposterior CFA—common femoral artery SFA—superficial femoral artery

stiff glide wire) may help. Occasionally, if one has trouble advancing the 5 French catheter, using a 4 French hydrophilic catheter may mitigate the problem. Attempts at passing the bifurcation should not be abandoned until several different angled catheters have been tried. If all such attempts fail and contralateral access is imperative, ipsilateral puncture with introduction of a snare to grasp the contralateral wire in the abdominal aorta should be considered. Alternatively, DSA may be performed from the aortic bifurcation; however, the contrast loads will be significantly higher in this situation.

Crossing of Lesion

The diagnostic imaging studies and the preliminary angiogram should suffice to identify a lesion that is amenable to endovascular therapy. Once such a lesion is identified, wire access across the target lesion is required to establish a platform for subsequent intervention.

Technique Iliac lesions may be approached either in a retrograde fashion from the ipsilateral CFA or in an antegrade fashion from the contralateral CFA if there is adequate working distance between the bifurcation and the iliac lesion. For more distal lesions, when a contralateral CFA approach is used, a guide sheath is required to stabilize catheters and wires. A wire is placed in the external iliac artery on the affected side (see above), and the diagnostic catheter placed across the bifurcation is replaced with a stiff sheath, such as a 6 French Balkin sheath (Cook Incorporated, Bloomington, Indiana), which has a curve that naturally rests over the bifurcation. Occasionally, it is difficult to get the sheath to cross the bifurcation. In such a situation, the initial wire may be exchanged for a stiffer wire, such as a 0.035-in. Amplatz wire (Cook Urological, Spencer, Indiana), and the sheath may be placed over this wire. The use of a reinforced or stiff guide sheath eliminates the mechanical disadvantage of a wire that moves away from the limb with all manipulations, and it solidifies unilateral limb access for subsequent angiography during the therapeutic portion of the procedure.

Once the sheath is in place, a long, angled end-hole catheter and a glide wire are directed toward the specific vessel segment being treated and carefully manipulated so as to cross the target lesion. Road mapping, fluoroscopy fade, or intermittent puffing of contrast material through the guide catheter can delineate the contours of the vessel, identify the correct path to take, and help keep the wire within the true lumen. In general, a stenosis can be crossed by a curved or J-tip wire, a 0.035-in. hydrophilic glide wire, or a Wholey wire (a 0.035-in. wire with a floppy tip; Mallinckrodt, St. Louis, Missouri). The hydrophilic coating on the glide wire makes it more prone to dissection than the other wires are. With angled catheters, it is essential to use torque devices to direct the tip of the wire in the appropriate direction. In some cases, using a TAD II wire with a 0.018-in. distal tip and a 0.035-in. main body (Mallinckrodt, St. Louis, Missouri) makes access through a tight lesion easier to obtain; in addition, it provides a transition to a larger, more robust wire, which can be a very effective platform. For tibial stenoses, a 0.014-in. or 0.018-in. system is generally employed to cross tighter lesions. To stabilize the 0.014-in. wire, a 3 or 4 French catheter may be used as a guide catheter, placed just proximal to the lesion.

Occlusions can be difficult to cross, particularly when significant calcification is apparent on the plain films obtained before angiography. The techniques employed are the same as those used to cross a stenosis. The goal is to traverse the occlusion and gain access to the true lumen distally; accordingly, a J-tip or Wholey

wire may be preferred, in that hydrophilic wires tend to create dissection planes. Often, the occlusion cannot be crossed, and a subintimal plane must be developed. A glide wire is used to gain access near the proximal portion of the lesion at a branch point and allowed to deform in such a way as to form a loop; the wire is then pushed forward, supported by a 4 or 5 French catheter. Often, the true lumen is accessed without any difficulty, and the location of the wire within the lumen is confirmed by contrast injections. Occasionally, however, reentry into the true lumen proves difficult. Various manipulations and techniques may be employed to help with this technical issue. In addition, two systems have been developed with this potential problem in mind. The CrossPoint IVUS catheter (Medtronic, Minneapolis, Minnesota) combines an intravascular ultrasound probe with a puncture needle and allows one to visualize the true lumen, enter it with a hollow needle, and pass a wire to maintain access. The Outback catheter (LuMend, Redwood City, California) has a special tip that microdissects the plaque to facilitate reentry into the true lumen. If these options fail, retrograde puncture and retrograde passage of a wire, with interval snaring to “floss” the occlusion, may be considered.

Troubleshooting In crossing occlusions, the following three points must be emphasized.

1. Care must be taken to ensure that the operator is in the true lumen.
2. To preserve subsequent bypass targets, the next segment of the vessel must not be compromised by an overly aggressive attempt to regain access from a subintimal dissection plane.
3. Wire access across the lesion must be maintained at all times.

A low-dose intravenous bolus of heparin (2,000 to 5,000 IU) must be given before any intervention to help prevent the thrombosis that may result from manipulation and transient occlusion of the lesion.

Angioplasty and Stenting

Technique *Angioplasty.* Angioplasty is the initial treatment for most lower-extremity lesions. It may be the only therapeutic intervention required, or it may be employed as a prelude to stent deployment as a means of ensuring that the arterial lumen is wide enough to allow free passage of a platform. Angioplasty balloons exist in several varieties, which are reviewed in more detail elsewhere [see 6:8 *Fundamentals of Endovascular Surgery*]. In general, a noncompliant balloon is chosen that is 1 to 2 mm smaller than the normal or anticipated final vessel diameter for the area of the vasculature being addressed. The normal vessel diameter may be estimated on the basis of operator experience, measured with a radiopaque ruler placed alongside the vessel, or quantitated with the calibration software available on most imaging systems.

Once the balloon has been successfully maneuvered into position across the lesion, it is inflated with a manual inflation device to allow controlled delivery of a defined pressure load. Inflation is continued until the waist of the balloon disappears or maximal balloon inflation pressure (8 to 15 atm on most standard balloons) is reached. If an optimally sized balloon or stent will not cross a highly stenotic lesion, preangioplasty dilatation with a lower-profile, smaller-diameter balloon is required.

If the lesion is in close proximity to or involves a bifurcation (e.g., the aortic bifurcation, the femoral bifurcation, or the tibioperoneal trunk), care must be taken to prevent occlusion of the other branching vessel during dilatation of the target lesion. To this end, most interventionalists advocate use of the so-called kissing balloon technique, which involves simultaneous dilatation or

Figure 1 Basic endovascular techniques: angioplasty and stenting. Shown is the so-called kissing balloon technique. The patient presented with bilateral claudication, a decreased ABI on exercise treadmill testing, and a duplex ultrasonogram that suggested iliac occlusive disease. (a) Illustration shows two balloons “kissing” in the common iliac arteries. (b) Radiograph shows two stents “kissing” in the iliac arteries.

stenting of both branching vessels of the bifurcation to preserve both lumina. This technique is most commonly employed for proximal common iliac artery lesions [see Figure 1]. Alternatively, one may place a guard wire in the unaffected vessel and use this wire as a safety measure if there is a danger of luminal compromise, or one may deploy a balloon in the unaffected ostium while the affected ostium is treated.

Stenting. Basic stent choices are discussed more fully elsewhere [see 6:8 *Fundamentals of Endovascular Surgery*]. Stents may be placed either primarily or as a secondary procedure when initial angioplasty yields inadequate results (generally defined as either greater than 30% residual stenosis or the occurrence of an angioplasty-related complication, such as arterial wall perforation or flow-limiting dissection). Stents are generally sized according to the normal diameter of the adjacent vessel; 10% to 15% oversizing is acceptable. If the stent will be crossing two vessel segments with mismatched diameters (e.g., the common iliac artery and the external iliac artery), it is preferable to use a self-expanding stent, which is better able to adjust to such mismatching. Treatment of specific arteries is discussed more fully in connection with management of chronic lower-extremity ischemia [see Procedures for Chronic Lower-Extremity Ischemia, below].

Adjuncts to angioplasty and stenting. Over the past few years, several innovative devices have been developed that expand on the basic concepts of angioplasty and stenting in the lower extremities. One such device is the PolarCath cryoplasty balloon (Boston Scientific, Natick, Massachusetts) [see Figure 2a]. This device delivers cold thermal energy to the vessel wall in the form of nitrous oxide (-10°C) and is inflated to a pressure of 8 atm. It is presumed that the freezing of the vessel allows a more controlled vessel wall injury

and concomitantly promotes apoptosis and reduces the restenosis response. To date, the PolarCath has been employed mainly in the SFA; it is currently being tested for use in the tibial vessels. In initial reports, anatomic patency rates in the femoropopliteal arteries have exceeded 80% at 1 year for TransAtlantic Inter-Society Consensus (TASC) grade A, B, and C lesions.³

Another such device is the Peripheral Cutting Balloon (Boston Scientific, Natick, Massachusetts) [see Figure 2b], which is increasingly being used on lower-extremity vascular lesions, particularly those that proved resistant to balloon angioplasty. This device consists of a noncompliant balloon that has four thin blades placed longitudinally around it; it is available in sizes ranging from 2 mm to 8 mm, and it operates over a 0.018-in. platform. The theoretical rationale for its use is that fracturing or cutting the lesion in a controlled pattern may reduce the severity of the vessel injury while achieving a satisfactory luminal response and mitigating the restenosis response. Initial results in stenotic vein grafts have been encouraging, with 95% patency reported at 11 months' follow-up in one small study.⁴

Directional atherectomy devices are being used to treat chronic atherosclerotic leg ischemia in the belief that debulking the lesion will allow greater increases in luminal diameter than the conventional methods of angioplasty and stenting, which merely displace plaque. Multiple different systems are available, all of which appear to be yielding roughly equivalent results. One of the more widely used directional atherectomy devices is the SilverHawk Plaque Excision System (FoxHollow Technologies, Redwood City, California), which consists of a catheter that is compatible with a 0.014-in. wire and that has a rotating blade at the tip. As the blade shaves plaque off the vessel wall, the shavings are stored in the tip of the catheter. When the storage unit in the tip becomes full, the catheter is removed and cleaned, then reinserted. Initial intermediate-term results have been satisfactory; however, wider

Figure 2 Basic endovascular techniques: angioplasty and stenting. (a) Shown is the PolarCath peripheral dilatation system, comprising an inflation unit, a cryoplasty balloon, a cord attached to a separate power module, and a nitrous oxide cartridge. (b) Shown is the Peripheral Cutting Balloon, with an enlarged view of an atherotome. (Images provided courtesy of Boston Scientific, Natick, Massachusetts).

use of this device will depend on the results of the multicenter TALON registry.⁵

Drug-eluting stents have become popular for use within the coronary circulation, but at present, they are only in the initial stages of investigation for treatment of lower-extremity arterial disease. Initial trials with the sirolimus-coated S.M.A.R.T. stent (Cordis, Miami Lakes, Florida) showed a nonsignificant trend toward decreased restenosis rates.⁶

Troubleshooting Angioplasty can result in either non-flow-limiting or flow-limiting dissections. If dissection occurs, reinflation of the balloon over the dissection for 5 to 10 minutes may anneal the flap to the wall. If balloon reinflation fails and flow is still disrupted, a stent should be placed.

In situ thrombosis of the vessel occasionally occurs after angioplasty or stent placement. If it develops in a patient who underwent angioplasty alone, the thrombosed vessel may be stented open. If this measure fails or if the in situ thrombosis develops after stent placement, a thrombolysis catheter is placed across the lesion and a single bolus of a thrombolytic agent administered. If this approach yields suboptimal results, an indwelling catheter is placed for a 12- to 24-hour infusion [see Procedures for Acute Lower-Extremity Ischemia, *below*]. Alternatively, mechanical thrombectomy with a rheolytic catheter may be considered. Finally, restenting with an open or covered stent is an option, but it may result in distal embolization.

Perforation of the vessel can occur during angioplasty or recanalization. Perforations that are small or that occurred during a failed recanalization need not be treated. Perforations associated with persistent extravasation of contrast may be managed primarily with balloon tamponade (20 minutes of inflation, with intermittent deflations to allow distal circulation and reversal of anticoagulation) and secondarily with placement of a covered stent.

Endoluminal intervention to treat plaque can result in distal embolization of cholesterol or plaque or distal dislodgment of thrombi. Mechanical or pharmacologic thrombolysis remains the mainstay option in such cases. If, however, one is concerned about

a possible nonthrombotic embolic event, aspiration or open embolectomy may be required to achieve satisfactory reconstitution of flow.

When a vessel is heavily calcified, a self-expanding stent may be unable to deploy and may be effectively “jailed” in the lesion. In this situation, wire access must be maintained, and a low-profile balloon should be used to enlarge the operating lumen so that a high-pressure balloon can then be introduced. The introduction of a series of balloons with successively larger diameters will eventually allow the stent to be deployed. Balloon perforation often occurs in these cases, and care should be taken to extract the perforated balloon intact.

Unplanned stent dislodgment is rare but not unknown. If it occurs, the errant stent may be fixed in place by placing an additional overlapping stent. Alternatively, a balloon may be inflated distal to the tip of the dislodged stent and used to move the stent to another vessel, where it may be safely deployed.

Complications The most common complications of angioplasty and stenting in the lower extremities are access-related issues, including hematoma, arteriovenous fistula formation, and pseudoaneurysm. The incidence of hematoma can be minimized by using the smallest sheath possible, waiting for normalization of the activated clotting time before pulling the sheath, and holding manual pressure for 30 minutes after the procedure. Devices designed for vessel closure after percutaneous intervention are available but have not been proved to reduce the incidence of access-related complications.⁷ With several of these closure devices, it is recommended that access of the groin not be attempted for up to 90 days after insertion.

PROCEDURES FOR CHRONIC LOWER-EXTREMITY ISCHEMIA

Preprocedural Evaluation

Patients presenting with chronic lower-limb ischemia are evaluated as previously outlined [see Basic Endovascular Procedures, Preprocedural Evaluation, *above*]. Patients with claudication are

Figure 3 Algorithm illustrates workup of patients with chronic lower-extremity ischemia.

managed medically by controlling risk factors, instituting exercise therapy, and providing advice on smoking cessation.⁸ In patients with disabling claudication, rest pain, or tissue loss, diagnostic imaging studies are performed with the intent of identifying and subsequently treating any lesion that is amenable to endovascular therapy [see Figure 3]. If an intervention is indicated, patients are pretreated with antiplatelet agents as appropriate.

Technique

Techniques and protocols for diagnostic angiography and accessing the target lesion have been outlined [see Basic Endovascular Procedures, *above*]. If it is unclear whether a vessel has a hemodynamically significant stenosis, arterial pressures can be measured across the lesion by connecting an end-hole catheter to a pressure transducer. A drop of more than 10 mm Hg in systolic blood pressure or more than 5 mm Hg in mean arterial pressure across the lesion is considered significant. The area in question

should also be subjected to a chemical challenge. Local intra-arterial delivery of a vasodilator (e.g., papaverine, 30 mg; prazosin, 25 mg; or nitroglycerin, 200 µg) will create distal vasodilatation, accentuate the translesional gradient, and, in many cases, unmask a significant lesion that might otherwise be missed.

Iliac lesions may be treated either by means of primary angioplasty, with stenting reserved for cases in which angioplasty yields unsatisfactory results, or by means of primary stenting. Either balloon-expandable or self-expanding stents may be used in the iliac vessels. Highly calcified lesions and lesions in smaller iliac vessels (< 7 mm) generally are best treated with self-expanding stents. Lesions in the external iliac artery or the femoral artery (including the CFA, the profunda femoris [PF], and the SFA) are best treated with angioplasty alone. In these vessels, stents usually are placed only when angioplasty has been unsuccessful or dissection or vessel rupture has occurred. As a rule, stenting for SFA lesions is best done with self-expanding stents, though very focal lesions may be treated with balloon-expandable stents. Stenting is relatively contraindicated in the popliteal artery; the extended range of motion across the nearby joint often leads to stent fracture. At present, stents are not used as primary therapy in infrapopliteal vessels. If stenting is required at infrapopliteal sites, coronary balloon-mounted platforms are the only available choices.

Postprocedural Care

After the procedure, patients require at least 2 to 12 hours of bed rest. Hydration with I.V. infusion of normal saline should be initiated, and appropriate dosages of renal-protective agents should be given. Aspirin, 81 mg/day, should be given on a long-term basis, and clopidogrel, 75 mg/day, should be administered for 30 days.

Outcome Evaluation

In most series, rates of technical success (defined as less than 30% residual stenosis) have exceeded 90%. Secondary patency rates for iliac interventions at 10 years have exceeded 50%.⁹ Angioplasty and stenting in the SFA have been studied, for the most part, in a retrospective fashion. Intermediate-term data have suggested patency rates of 70%, 60% and 50% at 1, 3, and 5 years, respectively. The reported clinical benefit has generally exceeded the anatomic patency rates.¹⁰⁻¹² None of the randomized studies published to date have found primary stenting to have any advantage over primary angioplasty in the femoral vessels.¹³⁻¹⁶ Factors indicative of a poor prognosis include intervention for more advanced limb ischemia, diabetes, complete occlusion (as opposed to stenosis), lesions longer than 10 cm, and poor distal runoff.⁸ The use of TASC criteria to stratify lesions anatomically helps predict which patients are likely to benefit most from endovascular therapy in the SFA.¹⁷ In one study that included almost 400 SFA interventions, patients who had TASC A and B lesions experienced significantly better outcomes than those who had TASC C and D lesions, with an overall 6-year patency rate of 52%.¹⁰ Currently, angioplasty is being evaluated for use in infrapopliteal disease. Some initial success has been reported, though it still appears that this approach is best reserved for patients in whom open surgical management is relatively contraindicated.¹⁸

PROCEDURES FOR ACUTE LOWER-EXTREMITY ISCHEMIA

Preprocedural Evaluation

The initial decision in managing acute lower-extremity ischemia limb should be whether to proceed directly to surgery or to obtain a diagnostic angiogram and consider endovascular therapy. The Working Party on Thrombolysis developed a consensus

Table 4 Contraindications to Thrombolysis

Relative Contraindications	Absolute Contraindications
Recent surgery (within 2 wk)	Active internal bleeding
Recent trauma (within 1 mo)	Recent stroke (within 2 mo)
History of coagulopathy	Intracranial pathology
Pregnancy or recent delivery	

on how to approach patients with acute arterial ischemia. The main message of this consensus was that classifying patients according to their grade of ischemia is essential to forming treatment plans [see 6:5 *Pulseless Extremity and Atheroembolism*].¹⁹ Grade IIa and early grade IIb ischemia may be amenable to endoluminal therapy, including thrombolysis. Established grade IIb ischemia is best treated by means of surgical embolectomy or thrombectomy, with intraoperative angiography, intraoperative thrombolysis, and over-the-wire embolectomy as options. Grade III ischemia is nonsalvageable and generally necessitates amputation [see 6:20 *Lower-Extremity Amputation for Ischemia*].

Arterial Thrombolysis

Thrombolysis, either pharmacologic or mechanical, is the mainstay of endovascular therapy for acute arterial ischemia.²⁰ Relative and absolute contraindications to thrombolytic therapy have been established [see Table 4].

Technique An initial diagnostic angiogram of the affected limb is obtained, with care taken to gain arterial access in such a way that thrombolytic therapy is not prevented. The standard approach is from the contralateral groin (see above). To reduce the chances of access site hematoma during administration of a thrombolytic agent, access should be gained at a substantial distance from the occlusion. Crossing the lesion involves identifying the origin of the occlusion. In cases of native vessel occlusion, this is generally a straightforward process. If a bypass graft is occluded, one may be able to visualize a stump of the graft, which will aid in direct management [see Figure 4]. The standard methods of crossing a stenosis or an occlusion [see Basic Endovascular Procedures, Crossing of Lesion, above] should be employed.

Once the lesion has been crossed securely with a wire, an infusion catheter (e.g., a 3 French multi-side-hole catheter) is advanced over the wire and situated in the occlusion. An infusion wire may also be inserted through the infusion catheter in a coaxial fashion and placed distally to increase the area of direct lysis, to protect the outflow vessel, or to address two separate lesions [see Figure 5]. The position of the catheter and the wire are then documented by means of fluoroscopy. With the infusion catheter left securely in place, the thrombolytic infusion is begun. Often, it helps to insert a guide sheath into the contralateral iliac system to prevent dislodgment and facilitate subsequent access.

Pharmacologic agents. The use of thrombolytic drugs has been refined over the past decade. In the United States, urokinase and tissue plasminogen activator (t-PA) have been the most widely used agents. Urokinase was popular in the 1980s and 1990s, but its temporary withdrawal from the market in 1998 because of manufacturing problems allowed physicians to become more comfortable working with t-PA. At present, recombinant t-PA (rt-PA) (e.g., alteplase) is the lytic agent most commonly used in the United States. Reteplase is a newer recombinant agent that is similar to rt-PA but has a longer half-life and a less specific affinity for

fibrin.^{21,22} To prevent buildup of clot around the sheath, all patients undergoing pharmacologic thrombolysis also receive heparin in a continuously administered low dosage (200 to 500 U/hr); higher dosages are associated with a substantially increased risk of hemorrhagic complications.

Mechanical adjuncts to thrombolysis. Several mechanical adjuncts are available to reduce thrombolytic time or enhance the completeness of clot dissolution. These adjuncts can also be beneficial when thrombolytic therapy is contraindicated.

Various mechanical thrombectomy systems are commercially available. One such system is the AngioJet system (Possis Medical, Minneapolis, Minnesota). The AngioJet consists of a pump drive unit and a 4 to 6 French catheter, which is passed over a 0.035-in. wire to the target area. The catheter has two lumens: one is used to pulse heparinized normal saline at a pressure of 10,000 psi, and the other contains the wire and serves as the route by which clot debris

Figure 4 Arterial thrombolysis. Patient presented with grade IIa ischemia, and duplex ultrasonography showed evidence of an occluded femoropopliteal reverse saphenous vein bypass graft. Angiogram taken from the ipsilateral external iliac artery demonstrating a patent but diseased CFA and a patent PF. The SFA is occluded. The stump of the occluded arterial bypass graft is visible (arrow).

Figure 5 Arterial thrombolysis. Follow-up imaging of the patient in Figure 4 illustrates the use of a thrombolytic infusion catheter. (a) Shown is the proximal end of the occluded CFA–popliteal artery bypass graft. (b) The infusion catheter (black arrow) is placed. (c) The infusion wire rests in the distal bypass graft (hollow arrow), increasing the infusion length for the thrombolytic agent.

is removed. The power pulse spray technique, with rt-PA added to the saline (10 mg in 100 ml) and delivered by the rheolytic catheter directly into the clot, may also be employed to help dissolve clot. In this technique, the system is modified so that the outflow circuit is closed and the unit pulses the saline–rt-PA mixture into the clot, allowing simultaneous lysis and maceration. Once the thrombus has been treated and an additional 15-minute interval has elapsed, conventional catheter therapy is employed to remove the clot and the residual rt-PA. The advantage of this approach is that it permits high-dose lysis while imposing only a low systemic load.²³ If more than 750 ml of saline is used with the AngioJet catheter during a single session, there is a significant risk of acute renal impairment secondary to hemolytic debris.

Also used for mechanical thrombectomy are wall-contact instruments such as the Arrow-Trerotola device (Arrow International, Reading, Pennsylvania). Such devices result in significant endothelial damage and distal clot embolization and thus are better suited for hemodialysis grafts. Another option is the Helix Clot Buster (ev3, Plymouth, Minnesota), which creates a vortex at the catheter tip that macerates the clot into microscopic fragments; it differs from the AngioJet in that it lacks an aspirating port. The Oasis thrombectomy catheter (Boston Scientific, Natick, Massachusetts) also fragments thrombus into small particles. The use of these devices in the setting of acute arterial occlusion was addressed in a comprehensive review published in 2001.²⁴ All of these devices may be used either in place of or in addition to pharmacologic thrombolysis.

At present, the evidence supporting the use of mechanical thrombectomy devices in the setting of acute limb ischemia is modest. One retrospective study demonstrated successful recanalization in approximately 60% of patients.²⁵ At our own institution, we have found these devices to be useful in decreasing the clot burden on the second or third t-PA check (24 to 36 hours after commencement of the infusion), after the clot has been softened by the initial pharmacologic lysis. It remains to be seen whether this approach reduces the overall time needed for thrombolytic therapy.

Over-the-wire embolectomy is another mechanical means of removing clot. Newer designs of the standard Fogarty embolectomy catheter have been developed that include an inner lumen, so that the catheter can be passed over a 0.035-in. wire. Use of these devices facilitates fluoroscopically guided embolectomy and ensures that the catheter can be passed to all target vessels. Over-the-wire embolectomy provides an efficient percutaneous method of removing clot without any need for the constant monitoring that pharmacologic thrombolysis requires.

This embolectomy technique may be supplemented by intraoperative catheter-directed thrombolytic therapy when postoperative imaging reveals residual clot or inadequate perfusion. Under fluoroscopic guidance, an end-hole catheter or a multi-side-hole infusion catheter is guided over a wire into the target vessel or vessels, and a thrombolytic agent (e.g., rt-PA, 0.5 mg/kg over 30 minutes) is directly infused with inflow occlusion. Imaging is recommended both before and after thrombolysis. Adjunctive use of an embolectomy catheter may also be beneficial. If, however, there is still no perfusion after adequate thrombolytic therapy and embolectomy, the situation generally is not retrievable, and alternative therapies should be explored. In the clinical trials of perioperative thrombolytic therapy published to date, success rates ranged from 64% to 100%. Bleeding was the most common complication.

Postprocedural care After the intervention, the patient is observed in a monitored unit by personnel trained in the management of thrombolytic therapy. Lower-extremity neurovascular examinations are carried out frequently (every 1 to 2 hours). The patient's clinical status is also monitored for evidence of bleeding, including access-site hematoma, neurologic changes, and hypotension. Repeat angiograms are performed at 12-hour intervals (or sooner if clinical examination reveals significant deterioration) to assess the progress of lytic therapy and to allow changes in catheter positioning. Some physicians recommend following fibrinogen levels and discontinuing the lytic agent if levels fall below 150 mg/dl. Other end points for the thrombolytic therapy are failure to

progress, complete lysis of the target thrombus, or significant bleeding complications necessitating discontinuance of lysis.

Once lysis is discontinued, the heparin dosage should be increased to achieve therapeutic levels of anticoagulation. Any lesions unmasked by thrombolytic therapy should be treated, either by endovascular means or with an open procedure. Whether long-term anticoagulation is indicated depends on the patient's circumstances and the specific cause of the thrombosis.

Troubleshooting Many of the issues raised in connection with basic arterial access techniques arise during attempts at thrombolysis. Occasionally, the interventionalist experiences significant difficulty in accessing an occluded bypass graft. Thrombolysis of these occluded grafts can often be facilitated by employing a double-puncture technique, in which both a retrograde and an antegrade puncture of a bypass graft are performed under ultrasonographic guidance, allowing the infusion catheters to be placed so as to cover the entire length of the graft [see Figure 6].²⁶ With this approach, there is no need for CFA puncture, which is often made difficult by the presence of scar tissue, and the problem of finding access to the graft takeoff is eliminated. If a lesion cannot be

crossed, the thrombolytic agent may be delivered just proximal to the lesion for 2 to 4 hours after initiation of therapy, but the chances of a good outcome with this approach are diminished.

Whereas it is common for clinical findings to worsen slightly (as a result of distal microembolization) before improving—the so-called storm before the calm phenomenon—dramatic worsening of the physical findings calls for urgent angiography. Possible reasons for ischemic progression include propagation of clot (treatable by performing open embolectomy or thrombectomy), displacement of the lysis catheter (treatable by repositioning the catheter), or distal embolization of clot resulting in obstruction of the principal runoff vessels (treatable by advancing the infusion catheter or wire more distally, employing a rheolytic catheter, or performing open embolectomy or thrombectomy).

Complications General access-site complications—including hematoma, pseudoaneurysm formation, ischemia to the contralateral leg from an occlusive sheath, nerve damage (which is more common with axillary or brachial puncture secondary to an axillary sheath hematoma), arterial dissection of the access vessel, and distal embolization of the clot—are also seen with thrombolyt-

Figure 6 Arterial thrombolysis. Illustrated is ultrasound-guided double puncture of an arterial bypass graft for thrombolysis.²⁶

Table 5 Prospective, Randomized, Controlled Trials of Arterial Thrombolytic Therapy

Trial (Date)	N	Lytic Agent	Limb Salvage Rate at 1 Yr (Surgery vs. Lytic Therapy)	30-Day Mortality (Surgery vs. Lytic Therapy)	Bleeding Complication Rate with Lytic Therapy

ic therapy. Bleeding complications have presented a significant hurdle for thrombolytic therapy. Early studies that used therapeutic doses of heparin and higher doses of thrombolytics reported unacceptable rates of intracranial hemorrhage and other bleeding complications. Currently, most physicians employ rt-PA doses in the range of 0.25 to 0.50 mg/hr without compromising results. Overall, rates of bleeding complications with urokinase and rt-PA range from 5% to 10%, and the incidence of intracranial hemorrhage is less than 2%.²² As with open surgical therapy, compartment syndrome can complicate reperfusion of the ischemic limb; this complication should be checked for on serial clinical examinations.

Outcome evaluation The use of thrombolysis to treat acute lower-extremity arterial occlusion has been extensively studied. The results of the major prospective, randomized trials [see Table 5] showed thrombolytic therapy to be equivalent to surgery with respect to limb salvage and mortality and superior with respect to the need for complex surgical intervention. Most of these major trials were performed with urokinase and t-PA. The information gained from them has helped surgeons determine which patients are good candidates for thrombolytic therapy. Factors predictive of successful thrombolysis include symptoms of less than 14 days' duration, prosthetic graft occlusion, and high medical risk for open operation. Factors predictive of a poor outcome include chronic occlusion, native artery occlusion, and a lesion that cannot be crossed with a wire.²⁷

PROCEDURES FOR LOWER-EXTREMITY ARTERIAL ANEURYSMS

Ultrasound-Guided Thrombin Injection

Pseudoaneurysms of the CFA are a complication of femoral access for therapeutic procedures and are often amenable to percutaneous therapy. The pseudoaneurysm is visualized with a 7.5-MHz duplex ultrasound probe. Contraindications to injection of the sac are the presence of a wide mouth and no discernible neck, the development of an arteriovenous fistula, compression of adjacent structures by the pseudoaneurysm, and skin changes overlying the pseudoaneurysm. If infection is a possibility, the procedure should not be attempted. The ABI should be determined and duplex ultrasonography of the groin performed before injection.

Once it is certain that the pseudoaneurysm meets the criteria for thrombin injection, the sac is injected in the fundus area, away from the native artery, under direct ultrasonographic visualization and after infiltration of a local anesthetic. Usually, 1,000 units of thrombin is injected, and injection may be repeated one or more times. With multilobar aneurysms, serial injections into each fundus may be required to achieve complete resolution.

Factors associated with successful treatment are a long, narrow pseudoaneurysm neck and a sac diameter smaller than 8 cm.

Overall success rates may exceed 95%. Complications include distal native artery thrombosis and distal embolization, which generally can be treated with I.V. heparin.²⁸

Placement of Covered Stent

Treatment of lower-extremity aneurysms with covered stents is currently being studied. Isolated iliac artery and SFA lesions, though rare, lend themselves to endovascular repair [see Figure 7]. Initial data suggest that repair of popliteal aneurysms with covered stents is also feasible in high-risk patients.²⁹ Newer stents are being developed that are better able to withstand the stresses imposed by the repetitive motion of the knee joint.

Venous Procedures

As endovascular therapy for arterial disease continues to evolve, techniques learned in the arterial tree are increasingly being applied to the venous system. At present, the main venous disease processes being treated with endovascular techniques are iliofemoral deep vein thrombosis (DVT) and superficial reflux of the greater saphenous system causing symptomatic varicose veins.

VENOUS THROMBOLYSIS

Lower-extremity DVT can have a significant impact on patients' quality of life. Multiple studies indicate that approximately 50% of patients experience postthrombotic syndrome (PTS) and that the majority of patients with PTS report that physical and emotional well-being are negatively affected.³⁰ The goals of venous lysis are to relieve obstruction and to preserve valve function.

Preprocedural Evaluation

If DVT is less than 1 month old, a trial of lytic therapy is appropriate. The ideal candidate for such therapy has a symptomatic clot with lower-extremity swelling, is young and mobile, is not in a hypercoagulable state, and has no contraindications to lysis. Currently, lytic therapy is more commonly employed in active patients, whose quality of life is more likely to be negatively affected by PTS. In cases of unprovoked DVT or recurrent DVT, a hypercoagulability workup is indicated.³¹ Venous thrombosis is discussed more fully elsewhere [see 6:6 *Venous Thromboembolism*].

Technique

The initial diagnostic venogram can be obtained via almost any venous access site. Our preference is to perform an ipsilateral popliteal vein stick with the patient in the prone position; the posterior tibial vein or the contralateral femoral vein can also be used. The popliteal vein is accessed with a micropuncture needle under ultrasonographic guidance by means of a Seldinger technique.

The micropuncture sheath is then replaced with a 5 French sheath over a 0.035-in. wire. The diagnostic venogram is performed through the sheath or with a straight multi-side-hole diagnostic catheter.

As in arterial thrombolysis [see Arterial Procedures, Procedures for Acute Lower-Extremity Ischemia, Arterial Thrombolysis, *above*], a 3 French infusion catheter is advanced over the wire and positioned within the clot. Longer lesions can be managed with a coaxial infusion catheter–wire system. The lytic infusion is started, and a low-dose intravenous heparin infusion is initiated through the sheath. Mechanical thrombectomy and power pulse spray thrombectomy can efficiently debulk thrombus and may be beneficial in patients with phlegmasia caerulea dolens.³² The patient is kept in a monitored floor bed, and repeat venograms are performed every 12 to 24 hours.

In some patients, May-Thurner syndrome (compression of the iliac vein by the overlying iliac artery) develops; it is treated by placing a venous stent in the iliac vein to help reduce the effect of external compression and presumably treat the initiating factor. Venous stents are larger than corresponding arterial stents in a given vascular bed. Because of the increased compliance of the venous wall, self-expanding stents are preferred for use in veins.

Once lysis either is complete or has been continued for 72 hours, the lytic infusion is stopped, and the heparin infusion is increased to therapeutic levels. The patient is placed on warfarin therapy and should be treated in accordance with current algorithms for DVT [see 6:6 Venous Thromboembolism].

Complications

Reported rates of bleeding complications after venous lysis are higher than those after arterial lysis, typically ranging from 10% to 15%.³³ Pulmonary embolism, though rare in this setting, is known to occur, presumably as a result of partially lysed clot breaking off. To prevent this complication, some authors advocate prophylactic placement of an inferior vena cava (IVC) filter.³⁴ Ongoing development and wider use of retrievable IVC filters may accelerate the application of this adjunctive technique.

Outcome Evaluation

In a large retrospective study of 312 cases of iliofemoral and femoropopliteal DVT treated with urokinase infusion, greater

than 50% lysis was achieved in 83% of the patients; 11% experienced complications, and 1% had pulmonary emboli.³³ Small prospective, randomized trials found that thrombolysis yielded increased patency and decreased venous reflux in comparison with standard anticoagulation therapy.³⁵ Retrospective studies indicated that this improved venous patency and valve function might translate into better quality of life than would be achieved with anticoagulation alone.³⁶

TREATMENT OF SAPHENOFEMORAL VENOUS REFLUX

The application of endovascular techniques to saphenofemoral venous reflux has significantly changed the treatment of this condition.³⁷ Over the past decade, two minimally invasive approaches have been developed to replace standard high ligation and stripping of the greater saphenous vein (GSV): radiofrequency ablation (RFA) and endolaser obliteration.

Preprocedural Evaluation

Initially, symptomatic varicose veins are treated conservatively, with compression stockings. If conservative methods fail to provide relief, a varicose vein–related complication develops, and there is evidence of significant superficial reflux on duplex ultrasonography, the patient may be considered for endovenous treatment of GSV reflux.

Preprocedural Planning

GSV ablation procedures may be performed either in an office or in an operating or procedure room. If an office setting is chosen, the patient must be able to tolerate a small amount of discomfort with light sedation. The interventionalist must be certified to deliver conscious sedation and must be laser qualified if providing laser therapy. The procedure room, whether in an office or a medical facility, should be equipped with a procedure table capable of a steep Trendelenburg position, a high-resolution duplex ultrasonography device, and the appropriate ablation equipment. For more symptomatic side-branch varicosities, stab avulsions may be needed; as a rule, these are best done in the OR.

Technique

RFA of GSV The development of the Closure system (VNUS Medical Technologies, Sunnyvale, California) has allowed

Figure 7 Placement of covered stent. Shown is endovascular repair of an external iliac artery aneurysm. The patient presented with left groin pain several months after undergoing urologic surgery. (a) CT scan demonstrates a left external iliac artery pseudoaneurysm. (b) Angiogram demonstrates the same pseudoaneurysm. (c) Shown is the left external iliac artery after covered stent placement successfully excluded the pseudoaneurysm.

the application of RFA to GSV reflux therapy. Before the procedure, the GSV is mapped by means of ultrasonography. The patient is placed in the Trendelenburg position with a tourniquet around the upper thigh. Access to the GSV is obtained at the knee with an introducer needle and a wire threaded into the vein, and the needle is then replaced with a proprietary sheath. The Closure catheter is threaded through the sheath, and the tip is placed under ultrasonographic guidance just proximal to the takeoff of the superficial epigastric vein at the saphenofemoral junction (SFJ). A mixture of normal saline (500 ml), 1% lidocaine with epinephrine (50 ml), and sodium bicarbonate (5 mg) is injected under ultrasonographic guidance through the sheath and into the area surrounding the GSV to provide anesthesia, improve impedance, and protect the overlying tissues from exposure to the heat (so-called tumescent anesthesia).

The Closure device is then connected to the RFA delivery system, deployed, and pulled back at a controlled rate (initially, 1 cm every 30 seconds), with both impedance and temperature checked periodically. Manual compression, particularly in the upper thigh, may help in obtaining optimal numeric values on the RFA unit, as well as increase the efficiency of ablation. After the catheter has been withdrawn into the sheath, it is removed, and ultrasonography is performed to confirm that the GSV has been obliterated.

Endovenous laser treatment of GSV Access to the GSV is obtained as in RFA (see above), and a wire is advanced under ultrasonographic guidance to a point above the SFJ. A 600 μ m laser fiber is placed over the wire and positioned just distal to the SFJ in the GSV. A tumescent anesthetic solution is injected. Laser energy is delivered (e.g., with an 810 nm diode laser) as the laser fiber is pulled back. One advantage endolaser obliteration has over

RFA is that the laser wire can be pulled back relatively quickly (up to 18 mm/min).

Complications

The most serious complication associated with any of these endovenous techniques is DVT. There have been several reports of DVT resulting from RFA of the GSV, with incidences as high as 16%.³⁸ As of September 2005, four instances of pulmonary embolism from these clots had been reported in the United States Food and Drug Administration's Manufacturer and User Facility Device Experience (MAUDE) database (<http://www.fda.gov/cdrh/maude.html>), with at least one patient dying of a pulmonary embolism after the procedure.

Lower-extremity DVT has also been reported after endovenous laser therapy. Other problems include saphenous nerve paresthesias along the course of the GSV, bruising, skin burns, and superficial phlebitis. If endovenous laser therapy fails to obliterate the GSV, the problem can be remedied by prompt high ligation at the time of ablation. Clot in the common femoral vein can be treated with standard anticoagulation. Clot abutting the common femoral vein can be treated with clopidogrel, 75 mg/day orally for 1 month; serial ultrasonograms should be obtained to confirm that the clot is not propagating.

Outcome Evaluation

Overall, good results are obtained with endovenous treatment of GSV reflux. In one study of patients who underwent RFA of the GSV, 85% of patients had complete occlusion of the GSV at 2 years, and 90% of all patients were free of GSV reflux at that time.³⁹ In a study of patients who underwent endolaser obliteration, similar results were obtained: ultrasonographic surveillance documented a 93% rate of complete GSV closure at 2 years.⁴⁰

20 LOWER-EXTREMITY AMPUTATION FOR ISCHEMIA

William C. Pevec, MD, FACS

Patients with infected, painful, or necrotic lower extremities can be restored to a better functional level by means of a properly selected and performed amputation. This procedure should be considered reconstructive and restorative. In what follows, I address amputations across the toe, the forefoot, the leg, and the thigh. Because Symes amputations and hip disarticulations are seldom appropriate on ischemic limbs, I omit discussion of these procedures.

General Operative Planning

Selecting the appropriate level of amputation is of primary importance for healing and preservation of function. For an ambulatory patient who has either a palpable pulse over the dorsal pedal or posterior tibial artery or a functioning infrapopliteal arterial bypass graft, amputation on the foot (either toe amputation or transmetatarsal amputation) is appropriate. For an ambulatory patient who has a palpable femoral pulse and a patent deep femoral (profunda femoris) artery, whose skin is warm at least to the level of the ankle, and who has no skin lesions on the proposed amputation flaps, amputation below the knee is appropriate. For a nonambulatory patient who has ischemic rest pain, ulceration, or gangrene, amputation above the knee is appropriate. Arterial reconstruction is not indicated if the extremity is nonfunctional. Below-the-knee amputation does not offer nonambulatory patients any functional advantage; moreover, it is less likely to heal and often results in a flexion contracture at the knee that leads to pressure ulceration of the stump. Above-the-knee amputation depends on pulsatile flow into the ipsilateral internal iliac artery for successful healing. Above-the-knee amputation is also necessary for a patient whose skin is cool at or above the midcalf or who has skin lesions at or proximal to the midcalf.

Several adjunctive measurements (e.g., transcutaneous oxygen tension and segmental arterial pressure) have been used to select the level of amputation but have not proved particularly helpful. Generally, these adjuncts can reliably determine a level of amputation at which healing is virtually ensured, but they cannot reliably determine the level at which an amputation will not heal. Consequently, reliance on such measures to select the level of amputation will result in an unnecessarily high percentage of more proximal amputations.

In most cases, definitive amputation can be accomplished in a single stage. Local cellulitis can usually be controlled beforehand with bed rest and systemic administration of antibiotics. Undrained pus or recalcitrant cellulitis, however, must be treated with débridement and drainage in advance of

definitive amputation. This can be accomplished with local soft tissue débridement, single-toe open amputation, or guillotine amputation across the ankle.

Careful preoperative medical assessment is essential. Lower-extremity amputation for ischemia is associated with a mortality of 4.5 to 18%,¹⁻⁹ owing to the poor overall condition of the patient population. Accordingly, optimization of cardiac and pulmonary function and control of systemic infection are mandatory.

Finally, the timing of elective amputation is crucial. Because the loss of a limb is a difficult and frightening thing for a patient to accept, there is a natural tendency to delay amputation for as long as possible. This tendency is understandable but must be weighed against the potential problems associated with delay, such as poor preoperative pain control, which leads to an increased incidence of postamputation phantom limb pain, and extended preoperative immobility, which leads to physical deconditioning and makes prosthetic limb rehabilitation more difficult. A preoperative consultation with a physiatrist can allay some of the patient's anxiety by addressing the expected postoperative course of rehabilitation and thereby removing some of the fear of the unknown.

Toe Amputation

Amputation of the toe can be done either across a phalanx or across a metatarsal bone; the latter procedure is commonly referred to as a ray amputation. Many of the perioperative issues are essentially similar for the two approaches; however, indications and operative details differ somewhat and thus will be described separately.

OPERATIVE PLANNING

As noted (see above), for a toe amputation to heal properly, there must be either a palpable pulse over the dorsal pedal or posterior tibial artery or a functioning bypass graft to an infrapopliteal artery. If tissue necrosis or infection is confined to the distal or middle phalanx, transphalangeal amputation is appropriate; if tissue loss or necrosis involves the proximal phalanx, ray amputation is indicated. If tissue necrosis or infection extends over the metatarsophalangeal joint, either transmetatarsal amputation of the entire forefoot or below-the-knee amputation is usually necessary (see below).

Multiple transphalangeal amputations are functionally well tolerated. If, however, ray amputation of the great toe or of more than one smaller toe is called for, it may be preferable to perform a transmetatarsal amputation of the forefoot. Adequate skin coverage may be difficult to achieve with a

great-toe or multiple-toe ray amputation. In addition, ray amputation of more than one of the middle toes often causes central deviation of the remaining outside toes, which can lead to ulcerations secondary to abnormal pressure points. Finally, loss of the first metatarsal head or of several of the other metatarsal heads results in abnormal weight bearing on the remaining metatarsal heads, which may give rise to late ulceration.

OPERATIVE TECHNIQUE

Transphalangeal Amputation

Digital block anesthesia is ideal for transphalangeal amputation. A 25-gauge needle is inserted into the skin over the medial aspect of the dorsum of the proximal phalanx and advanced until the bone is encountered. The needle is then withdrawn slightly, and a small amount of fluid is aspirated to confirm that the tip of the needle is not in a blood vessel. Next, 0.5 to 1.0 ml of lidocaine, 0.5% or 1.0% without epinephrine, is slowly injected. The needle is then carefully advanced medial to the bone until the tip can be felt pressing against (but not puncturing) the plantar skin. Again, the needle is withdrawn slightly, fluid is aspirated, and 0.5 to 1.0 ml of lidocaine is injected. The same technique is repeated on the lateral aspect of the proximal phalanx. In this way, all four digital nerve branches are blocked. If multiple toe amputations are required, an ankle block, epidural anesthesia, spinal anesthesia, or general anesthesia may be used.

An incision is made to create dorsal and plantar skin flaps. Typically, these flaps are equal in length; however, depending on the location of the skin lesion, either the dorsal flap or the plantar flap can be left longer [see Figure 1]. Care must be

Figure 1 Toe amputation: transphalangeal amputation. Transphalangeal amputation can be performed either with dorsal and plantar flaps of equal length (a) or with a plantar flap that is longer than the dorsal flap (b). The phalanx is transected at the level of the apex of the skin flaps (dashed line). The bone is transected through the shaft of the phalanx, never across the joint.

taken not to create excessively long flaps, which may lack sufficient perfusion for healing, or to create undermined bevels with the scalpel [see Figure 2], which will lead to epidermolysis of the suture line.

The incision is extended down to the phalanx, and the soft tissues are gently separated from the bone with a small periosteal elevator. All tendons and tendon sheaths are débrided because the poor vascularity of these tissues may compromise the healing of the toe. The phalanx is transected at the level of the apices of the skin incisions [see Figure 1]. Care must be taken not to leave the remaining bone segment too long: this places undue tension on the skin flaps and is a primary cause of poor healing. The best way of transecting the phalanx is to use a pneumatic oscillating saw. Manual bone cutters can splinter the bone, and manual saws can cause extensive damage to the soft tissues. The bone is always transected across the shaft; because of the poor vascularity of the articular cartilage, disarticulation across a joint typically leads to poor healing.

Hemostasis is achieved with absorbable sutures and limited use of the electrocautery. Excessive tissue manipulation and electrocauterization should be avoided. The skin edges are carefully approximated with simple interrupted nonabsorbable monofilament sutures; perfect apposition is necessary to maximize the potential for primary healing. The sutures must not be placed too close to the skin edges, because the heavily keratinized skin of the foot is easily lacerated. The final step is the application of a soft dressing.

Ray Amputation

For ray amputation [see Figure 3], spinal, epidural, or general anesthesia may be employed. A so-called tennis-racket incision is made—that is, a straight incision along the dorsal surface of the affected metatarsal bone coupled with a circumferential incision around the base of the toe. The goal is to save all available viable skin on the toe; this skin is used to ensure a tension-free closure, and any excess skin can be débrided later, at the time of closure. Again, undermined bevels are avoided. The incision is taken down to the bone, and the soft tissues are separated from the distal metatarsal bone with a periosteal elevator. Dissection must be kept close to the affected metatarsal head to prevent injury to the adjacent metatarsophalangeal joint, which can lead to necrosis of the adjacent toe. The metatarsal bone is transected across the shaft with a pneumatic oscillating saw. The tendons and the tendon sheaths are débrided.

Meticulous hemostasis is achieved with absorbable sutures and limited use of the electrocautery. The skin is approximated with simple interrupted nonabsorbable monofilament sutures [see Figure 4]. If sufficient viable skin was preserved, a flap of plantar skin is rotated dorsally, and the incision is closed in the shape of a Y. Alternatively, the medial and lateral edges are shifted (one proximally and the other distally), the corners are trimmed, and the incision is closed in a linear fashion. A soft supportive dressing is applied.

COMPLICATIONS

Complications of toe amputation include bleeding, infection, and failure to heal. Because even a small amount of bleeding under the skin flaps can prevent proper healing, meticulous hemostasis is mandatory. In most cases, infection

Figure 2 In a lower-extremity amputation, the skin is always incised perpendicular to its surface (a). Given the varying contours encountered during extremity amputation, it can be difficult to maintain the perpendicular orientation of the scalpel; however, an incision that undermines the proximal skin flap (b) will devascularize the epidermis and lead to necrosis of the suture line.

and failure to heal are attributable to poor patient selection and poor surgical technique; the usual result is a more proximal amputation.

OUTCOME

For optimal healing, there must be an extended period (2 to 3 weeks) during which no weight is borne by the foot that underwent toe amputation. Once healing is complete, the patient should be able to walk normally, with no need for orthotic or assist devices. Beginning ambulation too early can disrupt healing flaps and necessitate more proximal amputation, which lengthens the hospital stay and increases long-term disability. For these reasons, toe amputation in patients with arterial occlusive disease is not an outpatient procedure. Patients are kept on bed rest and instructed in techniques (e.g., use of a wheelchair, a walker, or crutches) that allow

them to function without stepping on the foot that was operated on. Hospital discharge is delayed until such techniques are mastered.

Transmetatarsal Amputation

OPERATIVE PLANNING

As noted (see above), transmetatarsal amputation is indicated if there is tissue loss in the forefoot involving the first metatarsal head, two or more of the other metatarsal heads, or the dorsal forefoot. It is contraindicated if there is extensive skin loss on the plantar surface of the foot or on the dorsum proximal to the midshaft of the metatarsal bones. The peroneus longus and the peroneus brevis insert on the proximal portions of the fourth and fifth metatarsal bones; if

Figure 3 Toe amputation: ray amputation. (a) A longitudinal incision is made along the dorsum of the shaft of the metatarsal bone of the affected toe. A circumferential incision is then made around the phalanx. The circumferential incision should be placed as distal on the toe as there is viable skin so that as much skin as possible is retained for closure of the wound. (b) The metatarsal bone is transected across its shaft, proximal to the metatarsal head; the joint is never disarticulated.

Figure 4 Toe amputation: ray amputation. (a) If adequate skin is available, a plantar flap can be rotated dorsally and the skin closed in a Y configuration. This closure is technically easy to perform; however, there is a risk of skin necrosis at corners A and B. (b) Alternatively, the skin can be closed in a linear fashion. Corners A and B are gently trimmed. Corner B is shifted distally toward point D as corner A is shifted proximally. A slight dog-ear will result at point E; however, it will diminish with time.

these insertions are sacrificed, inversion of the foot results, eventually leading to chronic skin breakdown from the side of the foot repeatedly striking the ground during ambulation. Transmetatarsal amputation is also contraindicated if there is a preexisting footdrop (peroneal palsy).

OPERATIVE TECHNIQUE

Spinal, epidural, or general anesthesia may be employed for transmetatarsal amputation. Placement of a tourniquet on the calf is a useful adjunctive measure. This step greatly reduces intraoperative blood loss. More important, the blood-

less operative field that results allows more accurate assessment of tissue viability and hence more precise selection of the level of amputation; in a field stained with extravasated blood, it is easy to leave behind nonviable tissue that will doom the amputation. Use of a tourniquet is, however, contraindicated in patients who have a functioning infrapopliteal artery bypass graft.

After sterile preparation and draping, the leg is elevated to help drain the venous blood, and a sterile pneumatic tourniquet is placed around the calf, with care taken to pad the skin under the tourniquet and to position the tourniquet over the calf muscles, where it will not apply pressure over the fibular head (and the common peroneal nerve) or other osseous prominences. The tourniquet is then inflated to a pressure higher than the systolic blood pressure. In patients who do not have diabetes mellitus, a tourniquet inflation pressure of 250 mm Hg is typically employed; in patients who have diabetes mellitus and calcified arteries, a pressure of 350 to 400 mm Hg is preferred.

An incision is made across the dorsum of the foot at the level of the middle of the shafts of the metatarsal bones, extending medially and laterally to the level of the center of the first and fifth metatarsal bones, respectively [see Figure 5]. The dorsal incision is curved proximally at the medial and lateral edges to ensure that no dog-ears remain at the time of closure. The dorsal incision is continued perpendicularly through the soft tissues on the dorsum down to the metatarsal bones. The plantar incision is extended distally to a point just proximal to the toe crease. Care is taken not to bevel the skin incisions.

A plantar flap is created by making an incision with the scalpel adjacent to the metatarsophalangeal joints; the incision is then carried more deeply to the level of the midshafts of the metatarsal bones on their plantar surfaces. The periosteum of the first metatarsal bone is scored circumferentially

with the scalpel, and the soft tissue is dissected away from the first metatarsal bone with a periosteal elevator to a point about 1 cm proximal to the dorsal skin incision. The first metatarsal bone is then transected perpendicular to its shaft at the level of the dorsal skin incision with a pneumatic oscillating saw. This process is repeated for each individual metatarsal bone, with care taken to follow the normal contour of the forefoot by cutting the lateral metatarsal bones at a level slightly proximal to the level at which the more medial bones are transected. All visible digital arteries are clamped and tied with absorbable ligatures. If a tourniquet was used, it is deflated at this time. All tendons and tendon sheaths are débrided from the wound.

Meticulous hemostasis is achieved with absorbable sutures and limited use of the electrocautery. Any sharp edges on the metatarsal bones are smoothed with a rongeur or a rasp. The wound is irrigated to flush out devitalized tissue and thrombus. The plantar flap is trimmed as needed. The dermis is approximated with simple interrupted absorbable sutures, and the knots are buried. Because the edge of the plantar flap is generally longer than the edge of the dorsal flap, the sutures must be placed slightly farther apart on the plantar flap than on the dorsal flap if perfect alignment is to be obtained. It is imperative to achieve the correct skin alignment with the dermal suture layer. Once this is accomplished, the skin edges are gently and perfectly apposed with interrupted vertical mattress sutures of nonabsorbable monofilament material. Finally, a soft supportive dressing with good padding of the heel is applied; casts and splints are avoided because of the risk of ulceration of the heel or over the malleoli.

COMPLICATIONS

If a tourniquet is not used, intraoperative blood loss can be substantial; the blood pools in the sponges and drapes, often out of the anesthesiologist's field of view. Consequently, good

Figure 5 Transmetatarsal amputation. The skin incisions are shown from various angles. The metatarsal shafts are divided in their midportions (dashed line). The metatarsal bone transection is at the level of the apices of the skin incision, and the lateral metatarsal bones are cut slightly more proximally than the medial metatarsal bones, in a pattern reflecting the normal contour of the forefoot.

communication between the surgeon and the anesthesiologist is crucial for preventing ischemic complications secondary to hemorrhage.

Postoperative complications include bleeding, infection, and failure to heal, all of which are likely to result in more proximal amputation. They can best be prevented by means of careful patient selection and meticulous surgical technique.

OUTCOME

For proper healing, postoperative edema must be avoided and the plantar flap protected against shear forces. To prevent swelling, the patient is kept on bed rest with the foot elevated for the first 3 to 5 days. This step is particularly important if the transmetatarsal amputation was performed simultaneously with arterial reconstruction, which carries a high risk of reperfusion edema of the foot. After 3 to 5 days, the patient is instructed in techniques for moving in and out of the wheelchair without stepping on the foot. The foot that was operated on should not bear any weight at all for at least 3 weeks; early weight bearing may disrupt the healing of the plantar flap and necessitate more proximal amputation.

Once healed, patients should be able to walk independently with standard shoes. There is, however, a risk that they may trip over the unsupported toe of the shoe. In addition, the pushoff normally provided by the toes is lost after transmetatarsal amputation, and this change results in a halting, flat-footed gait. These problems can be obviated by using an orthotic shoe with a steel shank (to keep the toe of the shoe from bending and causing tripping) and a rocker bottom (to provide a smooth heel-to-toe motion).

Guillotine Ankle Amputation

OPERATIVE PLANNING

Guillotine amputation across the ankle is indicated when a patient presents with extensive wet gangrene that precludes salvage of a functional foot (e.g., wet gangrene that destroys the heel, the plantar skin of the forefoot, or the dorsal skin of the proximal foot). In such patients, initial guillotine amputation through the ankle is safer than extensive débridement: the operation is shorter, less blood is lost, the risk of bacteremia is reduced, and better control of infection is possible. Guillotine amputation is also indicated in patients with foot infections who have cellulitis extending into the leg. Transection at the ankle, perpendicular to the muscle compartments, tendon sheaths, and lymphatic vessels, allows effective drainage and usually brings about rapid resolution of the cellulitis of the leg, thus permitting salvage of the knee in many cases in which the knee might otherwise be unsalvageable.

OPERATIVE TECHNIQUE

General anesthesia is preferred for guillotine ankle amputation; regional anesthesia is relatively contraindicated for critically ill patients who are in a septic state. Anesthesia is required for no more than 15 to 20 minutes.

A circumferential incision is made at the narrowest part of the ankle (i.e., at the proximal malleoli) regardless of the level of the cellulitis [see Figure 6]. This placement takes the line of incision across the tendons, thereby preventing bleeding from transected muscle bellies. The incision is then carried through

the skin and soft tissues to the bone. If the arteries are patent, the assistant applies circumferential pressure to the distal calf. The distal tibia and fibula are then divided with a Gigli saw. Hemostasis is achieved with suture ligation and electrocauterization. A moist dressing is applied.

OUTCOME

After the procedure, the patient is kept on bed rest and given systemic antibiotics. Formal below-the-knee amputation can be performed when the cellulitis resolves, usually within 3 to 5 days. Routine dressing changes are unnecessary—first, because they are painful, and second, because the decision to proceed with formal below-the-knee amputation is based on the extent of the cellulitis in the calf, not on the appearance of the transected ankle.

Below-the-Knee Amputation

OPERATIVE PLANNING

Below-the-knee amputation is indicated when the lower extremity is functional but the foot cannot be salvaged by arterial reconstruction or by amputation of one or more of the toes or the forefoot. Healing can be expected if there is a palpable femoral pulse with at least a patent deep femoral artery, provided that the skin is warm and free of lesions at the distal calf. Before formal below-the-knee amputation, infection should be controlled with antibiotic therapy, débridement, and, if indicated, guillotine amputation. It is advisable to obtain consent to possible above-the-knee amputation beforehand in case unexpected muscle necrosis is encountered below the knee.

As with any amputation, the surgeon's preoperative interaction with the patient should be as positive as possible.

Figure 6 Guillotine ankle amputation. The skin incision is made circumferentially at the narrowest portion of the ankle. The bones are then transected at the same level (dashed line).

A constructive perspective to convey is that the amputation, though regrettably necessary, is in fact the first step toward rehabilitation. A well-motivated patient whose cardiopulmonary status is not too greatly compromised can generally be expected to walk again, albeit at an increased energy cost. In this regard, a preoperative discussion with a physiatrist can be very helpful, as can a meeting with an amputee who is doing well with a prosthesis. By inculcating a positive attitude in the patient before the procedure, the surgeon can greatly improve the patient's chances of achieving full rehabilitation, as well as decrease the time needed for rehabilitation.

OPERATIVE TECHNIQUE

Epidural, spinal, or general anesthesia is appropriate for below-the-knee amputation. The lines of incision should be marked on the skin. The primary level of amputation is determined by measuring a distance of 10 cm from the tibial tuberosity [see Figure 7]. The circumference of the leg at this level is then measured by passing a heavy ligature around the leg and cutting the ligature to a length equal to the circumference. The ligature is folded into thirds and cut once more at one of the folds, so that two segments of unequal length remain. The longer segment of the ligature, which is equal in length to two-thirds of the leg's circumference 10 cm below the tibial tuberosity, is used to measure the anterior transverse incision; this incision is centered not on the tibial crest but on the gastrocnemius-soleus muscle complex. The shorter segment, which is one-third of the leg's circumference at this level, is used to measure the posterior flap; the line of the posterior incision runs parallel with the gastrocnemius-soleus complex. To prevent dog-ears, the medial and lateral ends of the anterior transverse incision are curved cephalad before meeting the posterior incision, and the distal corners of the posterior incision are curved as well.

Blood loss can be reduced by using a sterile pneumatic tourniquet. A gauze roll is passed around the distal thigh. The leg is elevated to drain the venous blood, and the tourniquet is applied over the gauze roll. The tourniquet is inflated to a pressure of 250 mm Hg (350 to 400 mm Hg if the patient has heavily calcified arteries). The assistant elevates the leg, and the incision on the posterior flap is made first, followed by the anterior transverse incision; this sequence helps prevent blood from obscuring the field while the incisions are being made. The incisions are carried fully through the dermis, and the skin edges are allowed to separate and expose the subcutaneous fat. Care is taken to keep the scalpel perpendicular to the skin so as not to bevel the incision, which can lead to necrosis of the epidermal edges [see Figure 2].

The anterior muscles are transected with the scalpel in a direction parallel to the transverse skin incision. The tibia is scored circumferentially, and a periosteal elevator is used to dissect the soft tissues away from the tibia for a distance of approximately 3 to 4 cm. The tibia is then transected just proximal to the transverse skin incision. Dividing the tibia more than 1 cm proximal to the anterior skin incision will cause the thin skin of the anterior leg to be pulled taut over the cut end of the tibia by the weight of the posterior flap, thereby leading to skin ulceration. The tibia is transected perpendicularly, with a cephalad bevel of the anterior 1 cm

Figure 7 Below-the-knee amputation. The transverse incision (A) is made 10 cm distal to the tibial tuberosity. Its length is equal to two thirds of the circumference of the leg at that level. The posterior incision (B) is made parallel with the gastrocnemius-soleus muscle complex. The length of the posterior flap is equal to one third of the measured circumference of the leg. The corners of the incisions are curved to avoid dog-ears.

to keep from creating a sharp point at the tibial crest [see Figure 8]. The tibia can be transected with either a Gigli saw or an oscillating saw; because of the unpleasant sound of the power saw, the Gigli saw is preferred if the patient is under regional anesthesia. Sedation should be augmented in awake patients before division of the tibia. Benzodiazepines provide good sedation and amnesia.

The lateral muscles are divided, and the fibula is scored circumferentially. A periosteal elevator is used to dissect the soft tissues away from the fibula to a point 2 to 3 cm cephalad to the level at which the tibia was transected. The fibula is then transected with a bone cutter at least 1 cm cephalad

to the tibial transection level. The distal end of the tibia is lifted with a bone hook, and division of the posterior muscles is completed with an amputation knife. The specimen is then handed off the field.

The anterior tibial, posterior tibial, and peroneal arteries and veins are clamped, and the tourniquet is released. Clamps are placed on all other bleeding vessels. The posterior tibial and sural nerves are placed on gentle traction and clamped proximally. The nerves are transected and ligated, and the proximal nerves are allowed to retract into the soft tissues so as to prevent painful neuromas at the end of the stump. All clamped structures are then ligated with absorbable ligatures. The nerves are ligated because their nutrient vessels can bleed significantly. The distal anterior tip of the tibia is smoothed with a rasp to decrease the risk of skin ulceration over this osseous prominence. The stump is gently irrigated to remove all thrombus and devitalized tissue and to reveal any bleeding sites that may have been missed. Electrocauterization is rarely necessary.

The deep muscle fascia—not the Achilles tendon—is approximated with simple interrupted absorbable sutures, with care taken to align the posterior flap with the anterior incision. The skin is approximated by placing simple interrupted absorbable sutures, with buried knots, at the dermal-epidermal junction (interrupted subcuticular sutures). A carefully padded posterior splint is applied to prevent flexion contracture.

COMPLICATIONS

The most common complications after below-the-knee amputation are bleeding, infection, and failure to heal, all of which are likely to result in a more proximal amputation, frequently accompanied by loss of the knee. Prevention of these complications depends on careful patient selection, preoperative control of infection, and meticulous surgical technique.

To walk with a prosthetic leg, the patient must be capable of fully extending and locking the knee; thus, flexion contracture at the knee is a major complication. Such contractures are usually attributable either to poor pain control or to non-compliance with knee extension exercises. Good perioperative analgesia is of vital importance because knee flexion is the position of comfort and the patient will be unwilling to extend the knee if doing so proves too painful. To maintain knee extension, the patient should be placed in a splint in the early postoperative period. Once postoperative pain has abated, the splint can be removed. At this point, the patient must be taught extension exercises, in which the quadriceps muscles are contracted to maintain the length of the hamstring muscles. If a patient spends all of his or her time in a sitting position with the knee flexed, a flexion contracture will quickly develop. Once this happens, the patient may find it very difficult to regain full knee extension, and without full knee extension, prosthetic limb rehabilitation is impossible.

Phantom sensation is a common complication after below-the-knee amputation but is rarely of any consequence. Phantom pain, on the other hand, can be devastating. Sometimes, phantom pain develops as a consequence of unintentional suggestions made to the patient by medical personnel

Figure 8 Below-the-knee amputation. In this lateral view of the right leg, the tibia is beveled anteriorly, and the anterior portion is smoothed with a rasp. The fibula is transected at least 1 cm proximal to the level of transection of the tibia.

who fail to distinguish between the two entities. For example, a patient remarks to a medical attendant that he or she can still feel the amputated foot and toes, and the attendant suggests in response that the patient has phantom pain; the patient then focuses on the sensation and exaggerates the severity of the foot and toe discomfort, setting up a cycle of ever-worsening pain. This scenario is even more likely if the patient had prolonged ischemic rest pain before the amputation. Phantom pain can be prevented by (1) encouraging early amputation in a patient with a hopelessly ischemic foot (while taking into account the patient's need to come to grips with the prospect of amputation), (2) providing good pain control in the early postoperative period, and (3) assuring the patient that phantom sensation after a below-the-knee amputation is common and that any discomfort in the foot immediately after the operation period will vanish once he or she begins walking again with a prosthetic leg.

Ulceration of the skin over the transected anterior portion of the tibia is another serious complication that may preclude successful prosthetic limb fitting. This complication is also best managed through prevention, which depends on meticulous surgical technique. As noted (see above), the anterior tibial crest must be carefully beveled and smoothed at the level of transection, and the tibia must not be transected more than 1 cm proximal to the anterior skin incision.

With a standard below-the-knee prosthetic leg, weight is borne on the femoral condyles, the patella, and the tibial tuberosity. Breakdown of the stump can occur if weight is borne on the distal portion of the stump. Several decades ago, Jan Ertl described a tibiofibular synostosis designed to allow distal weight bearing; however, this technique has not been widely adopted.¹⁰

OUTCOME

Shortly after the amputation, the patient should be encouraged to start working on strengthening the upper body; upper-body strength is critical for making transfers and for using parallel bars, crutches, or a walker. In patients who have preoperative intractable ischemic rest pain, postoperative administration of epidural analgesia can break the cycle of pain. Once postoperative pain is adequately controlled, patients are taught to transfer in and out of a wheelchair. A compression garment is used on the stump once the sutures have been removed and the stump is fully healed.

Prosthetic rehabilitation begins when the stump achieves a conical shape. Unfortunately, a number of patients who have undergone amputation for ischemia are unable to walk with a prosthetic limb because of comorbid medical conditions and general debility. In many cases, however, even if full ambulation is impossible, patients can maintain relative independence if the knee is salvaged by using a combination of a prosthetic leg and a walker for transfers and movement around the house.⁶

Above-the-Knee Amputation

OPERATIVE PLANNING

Above-the-knee amputation is indicated if the lower extremity is unsalvageable and there is no femoral pulse.

The presence of pulsatile flow into a well-developed ipsilateral internal iliac artery usually ensures healing, but even when there is more severe arterial occlusive disease in the pelvis, healing can sometimes be achieved. Above-the-knee amputation is also indicated if there is tissue necrosis or uncontrollable infection extending cephalad to the midleg. Above-the-knee amputation is the procedure of choice in the case of gangrene or ulceration of a completely nonfunctional lower extremity.

OPERATIVE TECHNIQUE

Epidural, spinal, or general anesthesia may be used for above-the-knee amputation. For the best functional results, it is desirable to keep the femur as long as possible. A longer stump improves the prognosis for prosthetic limb rehabilitation and provides better balance for sitting and transfers. Healing potential, however, is lower with a longer stump; therefore, if the pelvic circulation is severely compromised, a shorter stump should be fashioned.

Anterior and posterior flaps of equal length are marked on the skin. The flaps should be wide and long [see *Figure 9*], and their apices should be centered on the line dividing the

Figure 9 Above-the-knee amputation. Broadly based anterior and posterior flaps are created. The femur is transected along the dashed line, at the apices of the skin flaps. The skin flaps and the level of transection of the femur can be placed more proximally if clinically indicated.

anterior and posterior muscle compartments. The posterior incision is made first to minimize the presence of blood in the operative field. The anterior incision is made second and carried through the anterior muscles in a plane parallel to the skin incision. The skin incisions are carried through the dermis, and the skin edges are allowed to separate and expose the subcutaneous fat; as in other amputations, they should be perpendicular to the skin surface so as not to undermine the skin.

If the superficial femoral artery is patent, the artery and vein are isolated and clamped after the sartorius is divided but before the remainder of the anterior muscles are divided. The femur is scored circumferentially. The soft tissues are dissected away from the femur to the level of the apices of the flaps, and the femur is divided with an oscillating saw at this level. If the end of the resected femur extends beyond the apices of the flaps, the wound cannot be closed without

tension. The posterior flap is completed with an amputation knife, and the specimen is handed off the field.

All bleeding points are clamped and tied with absorbable sutures. The sciatic nerve is placed on gentle traction, clamped, divided, and ligated, and the transected nerve is allowed to retract into the muscles. The deep fascia is approximated with interrupted absorbable sutures, with adjustments made for any discrepancy in length between the two flaps. The skin is approximated by placing interrupted absorbable sutures, with buried knots, at the dermal-epidermal junction (interrupted subcuticular sutures).

A nonadherent dressing is placed on the suture line and covered with dry, fluffed gauze bandages. An aerosol tincture of benzoin is sprayed on the thigh, the hip, and the lower abdomen. When the benzoin is dry, a cloth stockinette with a diameter of 4 in. is stretched over the stump [see Figure 10]. The cuff of the stockinette is cut medially at the groin, and

Figure 10 Above-the-knee amputation. (a) After an aerosol tincture of benzoin is applied to the thigh, the hip, and the lower abdomen, a 4 in. wide stockinette is rolled over the amputation stump. The cuff of the stockinette is cut medially at the groin. (b) The remainder of the stockinette is then rolled laterally up over the hip, and the cuff is cut on the lateral midline. (c) The two resulting strips of cloth are passed around the waist, one anteriorly and one posteriorly, and these strips are tied on the anterior midline to complete the dressing.

the stockinette is rolled laterally above the hip, where the cuff is then cut on the midaxillary line. This process yields two strips of cloth, one anterior and one posterior, which are passed around the patient's waist and tied on the anterior midline.

If the patient is a candidate for prosthetic limb rehabilitation, a traction rope is passed through a hole cut in the distal end of the stockinette and tied. The rope is hung over the end of the bed and tied to a 5 lb weight; this step helps prevent flexion contracture at the hip.

The stockinette need not be removed for the wound to be inspected. A window is cut in the distal end of the stockinette, and the gauze is removed. Once the incision has been inspected, fresh gauze is applied, and the window in the stockinette is closed with safety pins.

COMPLICATIONS

Postoperative complications include bleeding, infection, and failure to heal, all of which are likely to result in the need for surgical revision of the amputation stump. Control of preoperative infection and meticulous surgical technique and hemostasis are necessary to prevent these complications.

Flexion contracture of the hip is a major complication of above-the-knee amputation. Such contractures preclude

successful prosthetic limb rehabilitation. In dealing with this complication, prevention is far more effective than treatment: once a flexion contracture at the hip becomes fixed, it is very difficult to reverse. If a patient is a candidate for prosthetic limb rehabilitation, the traction weight mentioned earlier (see above) can be very helpful. As soon as postoperative pain is controlled, the patient should be taught to spend three periods daily in a prone position to help extend the hip. He or she should then be taught exercises for maintaining range of motion in the hip before prosthetic limb rehabilitation is initiated. Flexion contracture of the hip is less of a problem in nonambulatory patients; however, it can still lead to wound breakdown and chronic skin ulceration.

Gottschalk noted that loss of the adductor magnus leads to abnormal abduction of the femur. Accordingly, he proposed preservation of the adductor magnus and myodesis of the transected muscles to the femur to improve the biomechanics after above-the-knee amputation.^{11,12}

OUTCOME

Once postoperative pain has abated, patients are mobilized to wheelchair transfers. The prognosis for successful prosthetic limb ambulation in patients undergoing above-the-knee amputation for ischemia is very poor.

Approach to Suspected Renovascular Disease

Vascular disease that affects the renal arteries is an increasingly common clinical scenario encountered by general and vascular surgeons. As a result of heightened clinical awareness and advances in vascular imaging, more patients than ever before are being identified as having some degree of atherosclerotic or fibromuscular renovascular disease. The vast majority of these lesions cause no symptoms, are hemodynamically insignificant, or both. Some, however, are severe enough to alter renal perfusion pressure, leading to changes in blood pressure regulation and renal function. Symptomatic renovascular disease can have a variety of manifestations, ranging from mild renovascular hypertension to congestive heart failure and ischemic nephropathy.

Our purpose in this chapter is to outline an approach to the diagnosis and management of renovascular disease that is based on an understanding of the relevant pathophysiology [see Discussion, Pathophysiology of Renovascular Hypertension, *below*]. The procedures employed for surgical and endovascular treatment of renovascular disease are described in greater depth in other chapters [see 6:22 *Open Procedures for Renovascular Disease* and 6:23 *Endovascular Procedures for Renovascular Disease*].

Incidence and Risk Factors

In the United States, hypertension affects approximately 24% of the entire population and 50% of persons over the age of 60 years.¹ It is an independent risk factor for increased cardiovascular morbidity and mortality: cardiovascular risk doubles for every 20/10 mm Hg increase in blood pressure.² In fact, it is the number-one modifiable risk factor associated with increased cardiovascular morbidity and mortality. Data from the National Health and Nutrition Examination Survey (NHANES) revealed that 30% of hypertensive persons in the United States were unaware that they had hypertension, that more than 40% of hypertensive persons were not being treated for their condition, and that in two thirds of hypertensive patients who were being treated, blood pressure was not maintained below the recommended target level of 140/90 mm Hg.

An estimated 90% to 95% of cases of hypertension are classified as essential or idiopathic, with the remaining 5% to 10% considered to be secondary to another cause. Secondary hypertension is sometimes refractory to usual medical treatment, the reason being that the underlying pathophysiologic state must be identified and treated in addition to the hypertension itself. There are many possible causes of secondary hypertension [see Table 1], and it can be difficult to determine which one is operative in a given clinical situation. As a result of the increasing use of diagnostic

imaging, renal artery stenosis (RAS) is frequently diagnosed in hypertensive patients. However, the precise contribution RAS makes to hypertension and renal dysfunction is not always clear, and therefore, the patient's response to treatment may not be readily predictable.

The natural history of RAS consists of continued narrowing of the renal artery. Studies in which duplex ultrasonography (DUS) was employed to follow untreated patients with greater than 60% renal artery stenosis documented a 20% progression of disease per year, with 11% of patients progressing to renal occlusion within 2 years.³ RAS is associated with loss of renal mass, which is a surrogate marker for renal function. Occlusion of a renal artery is associated with substantial loss of renal size and function. Historical studies of the clinical course of RAS suggested that chronic renal failure developed within 6 years in as many as 27% of patients with RAS.⁴

The two main conditions associated with RAS are atherosclerosis and fibromuscular dysplasia. The former accounts for the vast majority of renovascular lesions. Atherosclerotic RAS is typically located at the aortic orifice or the proximal renal artery and probably represents spillover of aortic atherosclerotic disease [see Figure 1]. It is most commonly found in patients older than 50 years who have signs of atherosclerosis in other vascular beds. RAS associat-

Table 1 Screening Tests for Secondary Causes of Hypertension

Diagnosis	Diagnostic Study
Chronic renal disease and salt retention	Serum creatinine, GFR
Renal artery stenosis	DUS, MRA, CTA
Primary hyperaldosteronism	24-hr urinary aldosterone
Pheochromocytoma	24-hr urinary metanephrine, normetanephrine
Cushing syndrome or chronic steroid use	History, cortisol, dexamethasone suppression test
Thyroid or parathyroid disease	TSH, calcium, serum PTH
Coarctation of aorta	CTA
Sleep apnea	Sleep study with oxygen saturation
Effect of medication	History, drug screen

CTA—computed tomographic angiography DUS—duplex ultrasonography GFR—glomerular filtration rate MRA—magnetic resonance angiography PTH—parathyroid hormone TSH—thyroid-stimulating hormone

Approach to Suspected Renovascular Disease

Figure 1 Shown is severe bilateral RAS with poststenotic dilation in a severely diseased aorta.

ed with fibromuscular dysplasia is usually seen in patients younger than 40 years and usually affects the middle and distal segments of the renal artery. These lesions have a characteristic “string of beads” appearance.

Population-based studies indicate that hemodynamically significant atherosclerotic RAS is present in approximately 6% of persons older than 65 years, with a somewhat higher incidence in men (9.1%) than in women (5.5%). Incidental RAS is seen in approximately 20% of patients undergoing coronary angiography and in 35% to 50% of patients undergoing peripheral vascular angiography for occlusive disease of the aorta and the lower extremity. The prevalence of renovascular disease corresponds to the overall atherosclerotic burden. In the vast majority of patients, no direct causal relation between significant RAS and hypertension or ischemic nephropathy can be identified. Efforts to define such a relation are confounded by the fact that the same population in which renovascular disease is prevalent is also at risk for essential hypertension, diabetes, and baseline renal insufficiency. Other risk factors associated with renovascular disease include smoking, increased age, and hyperlipidemia.

RAS is believed to be the cause of hypertension in only 3% to 5% of the 90 million hypertensive persons in the United States. In those with mild hypertension (the vast majority), it plays only a negligible role; however, it plays a significantly larger role in those with severe systemic hypertension. (The severity of a case of hypertension is related to the patient’s blood pressure without medication, not necessarily to the difficulty or ease with which blood pressure can be controlled medically.) At the extremes of age (i.e., in the very young and the elderly), severe hypertension is substantially more likely to be renovascular than essential in origin [see Table 2].

Patients with RAS are at higher risk for cardiovascular morbidity and mortality than similar patients without RAS are. One series, in which patients underwent renal angiography after coronary angiography, found that 4-year survival was significantly decreased in patients with incidentally discovered RAS.⁵ Several series have suggested that the risk of adverse cardiovascular events is high in this population and exceeds the risk that might have been expected on the basis of the severity of hypertension.^{6,7} Blood pressure control—measured by the number of antihypertensive medications used, as well as by systolic and diastolic pressures—is the most commonly used end point in series examining treatment

of RAS. These studies make the points that cardiovascular risk is high in RAS patients and that blood pressure control may be a poor surrogate for clinical outcome. At present, it is not known whether the higher cardiovascular morbidity and mortality associated with RAS are attributable to the effects of renal ischemia or to the systemic effects of activation of the renin-angiotensin-aldosterone system (RAAS) [see Discussion, Pathophysiology of Renovascular Hypertension, below] or whether RAS is simply a marker of more advanced atherosclerotic disease.

Ischemic nephropathy may be defined as a progressive decline in renal function secondary to global renal ischemia. It is estimated that for 5% to 15% of the patients in whom end-stage renal disease necessitating dialysis develops each year, ischemic nephropathy is the underlying cause of the decline in renal function.^{8,9}

Investigative Screening Studies

Screening for suspected RAS is performed to identify those patients who are most likely to benefit from renal artery interventions aimed at managing hypertension or renal insufficiency. The decision regarding which screening test or tests to perform is not, however, a simple and obvious one. All of the noninvasive studies currently in use have their strengths and weaknesses, many of which are institution dependent. Constant improvements in technology and institutional variations in reporting standards, techniques, and published results have further complicated the process of determining the optimal first-line screening method. A variety of physiologic tests have been employed to screen for RAS and assess the contribution of RAS to hypertension or ischemic nephropathy. Peripheral plasma renin assays, rapid-sequence intravenous pyelography (for indirect assessment of differences in renal filtration), and isotope renography have all proved insufficiently sensitive to be useful for screening purposes. Catheter-based angiography has been widely used to screen for RAS, but technical improvements in DUS, computed tomographic angiography (CTA), and magnetic resonance angiography (MRA) have caused many physicians to prefer one or another of these imaging modalities for this purpose. A thorough understanding of the strengths and limitations of all of the screening tests, as well as an informed awareness of specific institutional limitations, is required to define the place of each test in one’s preferred diagnostic approach.

IMAGING

Contrast Arteriography

Of the several noninvasive or functional studies that are used to diagnose RAS and renovascular hypertension, none has displaced catheter-based contrast arteriography from its role as the diagnostic gold standard. In many institutions, however, CTA is now considered preferable to formal catheter-based arteriography as an easily reproducible screening test for RAS. The obvious drawback of CTA, as compared with the other imaging modalities, is the necessity of administering iodinated contrast material and the consequent risk of contrast-induced nephropathy (CIN). We frequently use CTA for the diagnosis of RAS in cases where concomitant aortoiliac aneurysmal or occlusive disease is suspected [see Figure 2].

“Drive-by” renal arteriography In a 1992 study of screening renal angiography (the largest such study published to date), 1,235 consecutive patients underwent renal arteriography at

Table 2 Clinical Clues to Diagnosis of Renal Artery Stenosis

Onset of hypertension at extremes of age (< 30 or > 60 yr)
Severe hypertension at > 55 yr
Accelerated, resistant, or malignant hypertension
Unexplained renal insufficiency or failure
Renal dysfunction associated with initiation of ACE inhibitor or ARB therapy
Unexplained congestive failure, pulmonary edema, or both
Unexplained atrophic kidney or size discrepancy between kidneys
Abdominal bruit

the conclusion of coronary angiography.¹⁰ Approximately 30% of these patients were found to have evidence of RAS, and 15% had greater than 50% stenosis. A 2001 study confirmed that RAS is associated with an increased risk of myocardial infarction, stroke, and death and that its presence in patients with coronary disease doubles the risk of mortality even when coronary revascularization is performed.⁵ This same study found that the severity of RAS was also predictive of mortality: 4-year survival was significantly lower (47%) in patients with bilateral RAS than in those with unilateral RAS (59%). The addition of nonselective renal arteriography in cases where the patient's serum creatinine concentration was lower than 2.0 mg/dl was associated with minimal additional cost and no clinically significant deterioration in renal function.

In 2006, on the basis of the findings from these studies, the American Heart Association (AHA) published a science advisory that made recommendations concerning routine renal arteriography in patients undergoing coronary angiography.¹¹ The AHA concluded that screening renal arteriography can reasonably be performed at the time of cardiac catheterization in patients at increased risk for RAS who are candidates for revascularization; however, it made no recommendation regarding concomitant treatment of RAS discovered during cardiac catheterization. In most cases, such a combined intervention is not feasible, whether because of the lack of preprocedural informed consent about renal artery endovascular intervention, the risk of CIN, or both.

Duplex Ultrasonography

In many institutions, including our own, renal artery duplex ultrasonography (RADUS) is currently used as the first-line screening test for RAS. Compared with other imaging modalities, RADUS has several unique advantages. In B mode, it provides direct images of the renal arteries, as well as a clear picture of contralateral kidney size (see below). It allows ongoing surveillance of lesions and interventions. It also achieves excellent imaging through renal stents, which on MRA appear only as flow voids. Finally, unlike CTA or even gadolinium-enhanced MRA, RADUS carries no risk of CIN.

Before RADUS is performed, the patient should fast overnight, should be given simethicone (to minimize interference on the images caused by bowel gas), or both. The study is done from both the anterior approach and the oblique flank approach; the latter is particularly helpful in obese patients, whose body habitus may severely limit the accuracy of the study. The renal arteries are imaged at their aortic origin and in their middle and distal segments. The peak systolic and end-diastolic arterial velocities are measured in

B mode with a Doppler angle of less than 60°. The ratios between the velocities in the renal artery and those in the aorta are determined, and the Doppler spectral waveform is recorded [see Figure 3]. The normal Doppler spectral waveform of the low-resistance renal vascular bed shows continuous diastolic flow.

Figure 2 CTA in a woman with a 7 cm infrarenal abdominal aortic aneurysm and chronic renal insufficiency shows severe bilateral stenosis of the renal artery origins and small, atrophic kidneys.

Figure 3 DUS focused on the proximal left renal artery reveals severe stenosis with markedly elevated peak systolic velocity (PSV) and end-diastolic velocity (EDV).

The size of the contralateral kidney is a useful surrogate marker for kidney function. A significant discrepancy in size and mass between the two kidneys should prompt the ultrasonographer to search for significant RAS or an occluded renal artery.

Doppler examination of the renal parenchyma is also employed as a means of indirectly evaluating RAS. This technique, performed via a flank approach, is very useful with obese patients and with cases in which examination is hindered by the presence of bowel gas. The acceleration time (the interval from the onset of the upstroke of the arterial waveform to the systolic peak), the acceleration index (the slope of the acceleration curve), and the resistive index (a measure of the resistance within the renal circulation) are determined. There is evidence to suggest that a normal resistive index (< 80) before renal revascularization (whether endovascular or surgical) predicts improvement with respect to blood pressure, renal function, and freedom from dialysis.¹² The resistive index itself, however, is not useful in predicting the degree of stenosis, because it may already be elevated in elderly patients and those with renal parenchymal disease.

One disadvantage of RADUS is that the diagnostic value of the images can be limited by the patient's body habitus or the presence of overlying bowel gas. In addition, RADUS can be time consuming to perform (requiring 30 to 60 minutes), and its accuracy is highly dependent on the experience of the ultrasonographer. Finally, polar or accessory renal arteries can easily be missed on RADUS, potentially leading to a false negative study result.

enhanced MRA is the technique of choice, in that the presumably less nephrotoxic gadolinium enhances visualization of the renal arteries. Multiplanar reconstruction (MPR) and maximum-intensity projection (MIP) techniques provide three-dimensional anatomic detail that is superior to what can be obtained with contrast arteriography [see Figure 4]. On a two-dimensional arteriogram, vessel overlap can cause the examiner to miss a severe stenosis; this problem rarely arises with three-dimensional images. We find renal MRA to be especially helpful in evaluating patients with RAS and ischemic nephropathy necessitating endovascular intervention.

Before the intervention is carried out, we review the axial MRA images of the aorta and the origins of the renal vessels. Working from these images, we rotate the image intensifier camera so as to obtain a perpendicular view of the renal orifice [see Figure 5]. This step allows us to use smaller quantities of contrast material and cannulate the renal orifice more quickly during endovascular intervention. It must be kept in mind that MPR and MIP postprocessing techniques are well known to exaggerate or even create the appearance of a stenosis and that the original source axial images must therefore be evaluated. The three-dimensional data set is digitally subtracted from the precontrast source images to create the contrast MRA images. Other signs of significant RAS include poststenotic dilation, loss of cortical medullary differentiation, and delayed renal enhancement or asymmetric filling of the collecting system during contrast injection.

The utility of MRA can be limited by several factors that are capable of degrading the acquired data. The presence of nearby metal (e.g., clips or stents) and air-tissue interfaces can lead to focal signal drop-out and simulate stenosis or obstruction. Movement by the patient during the scan (or even bowel peristalsis) can result in degraded, blurred images. The timing of the contrast bolus must be right to ensure adequate visualization of the arterial vessels. A contrast bolus that is delivered too late will not opacify the vessels and will appear as a stenosis, whereas a bolus that is

Magnetic Resonance Angiography

Many practitioners prefer MRA as the initial screening test for RAS. One advantage of renal MRA in this setting is that the quality of the results is less dependent on operator technique than is the case with RADUS. Gadolinium-

delivered too early will opacify the veins, resulting in so-called venous contamination of the images. We have found that the image quality attained with MRA is highly dependent on the institution where it is performed.

MRA is contraindicated in patients with pacemakers, automatic implantable cardioverter defibrillators (AICDs), brain aneurysm clips, cochlear implants, or metal fragments in the eyes. It is not contraindicated in patients with vascular stents, coils, or inferior vena cava filters, nor is it contraindicated in those with metal orthopedic devices, heart valves, or dental devices and materials.

Captopril Renal Scintigraphy

Radionuclide imaging is a noninvasive and safe means of evaluating renal blood flow and excretory function. The addition of an angiotensin-converting enzyme (ACE) inhibitor, such as captopril, to isotope renography improves the sensitivity and specificity of the test. In the presence of unilateral RAS, administration of captopril is associated with a 30% reduction of the glomerular filtration rate (GFR) in the affected kidney. The contralateral kidney shows a rise in the GFR, an increase in urine flow, and enhanced salt excretion, leading to marked retention of the isotope in the cortex of the affected kidney. The presence of significant renal dys-

Figure 4 (a) Gadolinium-enhanced MRA reveals signal dropout (flow void) at the origin of the left renal artery, signifying severe stenosis. (b) Axial MRA image reveals severe right renal artery stenosis.

Figure 5 For optimal viewing of the right renal artery during endovascular intervention, the C arm should be set to a 30° left anterior oblique position. Evaluation of axial MRA images before the procedure is begun facilitates cannulation and limits the amount of contrast material used.

function at baseline (serum creatinine concentration greater than 2.0 mg/dl), bilateral RAS, or both adversely affects the sensitivity and specificity of captopril renal scintigraphy, thereby limiting its utility as a screening test. In addition, the necessity of discontinuing ACE inhibitors and angiotensin-receptor blockers (ARBs) before the study may preclude the use of this test in patients with severe hypertension. Improvements in DUS, CTA, and MRA have now relegated captopril renal scintigraphy to secondary status as a screening modality.

Contrast-Induced Nephrotoxicity

The increasing use of diagnostic imaging studies (e.g., CTA and MRA) and catheter-based interventions in patients with significant RAS has made treatment and prevention of CIN important issues in this patient population. Current strategies for preventing CIN have generally involved one of three approaches: (1) providing hydration, (2) using low-osmolar or iso-osmolar iodinated contrast agents, and (3) administering the free radical scavenger N-acetylcysteine.

Intravascular volume depletion is an important risk factor for the development of CIN. Although to date, no randomized, controlled trials comparing hydration with placebo have been published, it has been standard practice for some time to institute hydration (usually intravenous) before administering a contrast agent. A small randomized, controlled trial from 2003 that compared I.V. hydration (0.9% saline, 1 ml/kg, starting 12 hours before infusion of contrast material) with unlimited oral fluid intake found I.V. hydration to be far superior for preventing CIN.¹³ In a subsequent study, 119 patients at a single center were randomly assigned to receive a 154 mEq/L infusion of either sodium chloride or sodium bicarbonate both before and after administration of contrast material (starting with a 3 ml/kg bolus 1 hour before contrast administration and continued at a rate of 1 ml/kg/hr for 6 hours afterward).¹⁴ Sodium bicarbonate hydration was found to reduce the incidence of CIN from 13.6% to 1.7%. Although this study is probably underpowered from a statistical perspective, the findings are suggestive. Sodium bicarbonate hydration is inexpensive and well tolerated and has become standard practice at most institutions.

The optimal choice of contrast media for preventing CIN has also been a subject of debate. There is evidence that the use of iso-osmolar nonionic contrast agents (e.g., iodixanol [Visipaque; GE Healthcare, Princeton, New Jersey]) yields significantly lower rates of CIN than the use of low-osmolar contrast agents (e.g., iohexol [Omnipaque; GE Healthcare, Princeton, New Jersey]) in

patients with diabetes or baseline renal insufficiency who undergo cardiac or vascular angiography.¹⁵

N-acetylcysteine, a thiol-containing antioxidant, is believed to act as a free-radical scavenger to prevent toxic effects on the renal tubular epithelium. Multiple clinical studies have examined the question of whether administration of *N*-acetylcysteine is beneficial in preventing CIN, but the results have been mixed. Although pooled meta-analyses have recommended giving *N*-acetylcysteine to patients who are at high risk, the overall effect of this measure is small in comparison with that of simple hydration. Nevertheless, *N*-acetylcysteine is inexpensive and generally well tolerated, and its use in those at high risk for CIN may reasonably be recommended.

On the basis of the existing evidence regarding prevention of CIN, we routinely preadmit patients with baseline serum creatinine concentrations higher than 2.5 mg/dl for overnight hydration, usually with saline; we then switch to sodium bicarbonate hydration (see above) before administering the contrast agent. We also use *N*-acetylcysteine (600 orally twice daily on the day before, the day of, and the 2 days after contrast administration) in this high-risk patient subset. Patients with serum creatinine concentrations between 1.5 and 2.5 mg/dl receive sodium bicarbonate hydration on the day of the procedure. We try to limit the amount of contrast material given during the procedure, and we currently favor iodixanol over iohexol in patients with baseline serum creatinine concentrations higher than 1.5 mg/dl or other risk factors for CIN (e.g., diabetes or a solitary kidney). Because of its substantial cost, we do not routinely use iodixanol in all patients. Well-hydrated persons with normal renal function receive I.V. saline before and after the procedure. In such patients, we routinely use iohexol, without other adjuncts.

LABORATORY TESTS

Renal-Vein Renin Assay

When hemodynamically significant RAS is found, functional studies may be indicated to determine the physiologic significance of the lesion. One such study involves measuring the renin concentration in blood samples from the two renal veins to determine whether unilateral renin hypersecretion is occurring. If the ratio of the renin concentration in the affected side to that in the unaffected side is greater than 1.5, the assay is considered to have yielded a positive result. The sensitivity and specificity of this test are diminished by the presence of bilateral RAS or RAS of a solitary kidney. Other factors that may reduce the reliability of the results include the inherent limitations of the renin assay itself and the potential for sampling errors. Because of the invasive nature of the selective renin assay and the concerns about its accuracy, we do not routinely use this test in RAS patients.

Management

MEDICAL THERAPY

Given the known association between RAS and systemic cardiovascular disease, medical treatment aimed at preventing or retarding further progression of systemic atherosclerosis is clearly a paramount concern in the management of RAS patients. Measures for modifying cardiovascular risk factors include effective blood pressure control, weight reduction, smoking cessation, lipid-lowering therapy, and antiplatelet therapy. It is the responsibility of the surgeon evaluating a patient with RAS to use this opportunity to ensure

that appropriate cardiovascular risk factor modification measures are being undertaken. After consultation with the patient's primary care provider, we routinely provide prescriptions for a cholesterol-lowering medication (e.g., a 3-hydroxy-3-methylglutaryl coenzyme A [HMG-CoA] reductase inhibitor) and an antiplatelet drug (e.g., acetylsalicylic acid [ASA]) if the patient has not already been taking these agents.

It is worth remembering that although medical treatment may lead to significant reductions in cardiovascular morbidity and mortality, no medical therapy has yet been shown to prevent the progression of ischemic nephropathy and renal failure. For patients with these latter conditions, renal revascularization is likely to be preferable to medical therapy.

Antihypertensive Agents

Both ACE inhibitors and ARBs have proved to be safe and effective for the treatment of hypertension in the setting of renovascular disease. In addition to their effects on the RAAS, these agents have been shown to reduce proteinuria and glomerular scarring in patients with a variety of renal diseases. Close clinical supervision is necessary when ACE inhibitors or ARBs are given to patients with renal insufficiency or failure. In this population, serum creatinine and potassium levels should be obtained weekly for 2 to 3 weeks after antihypertensive therapy with an ACE inhibitor or an ARB is started. These patients are at increased risk for acute renal failure (ARF); if ARF develops, the medications should be promptly discontinued. Patients with significant RAS who take ACE inhibitors or ARBs are also at risk for ARF when severely dehydrated; accordingly, they should be instructed to refrain from taking these agents when affected by severe vomiting, diarrhea, or dehydration. As a rule, ARF that occurs in this latter setting responds rapidly to fluid rehydration and temporary suspension of the ACE inhibitor or ARB. Once renal function has returned to baseline, the medications can usually be safely restarted.

It is important to be aware that some antihypertensive drugs may be associated with lack of energy (e.g., beta blockers and calcium channel blockers) or chronic cough (ACE inhibitors), either of which may have substantial effects on patient compliance. Several studies have shown that as many as 50% of such medications are changed or discontinued within 6 months. Proponents of renovascular revascularization have cited such studies as evidence favoring aggressive use of open or endovascular treatment of RAS over reliance on medical therapy alone.

Lipid-Lowering Agents

Lipid-lowering therapy with HMG-CoA reductase inhibitors (also referred to as statins) effectively reduces total and low-density lipoprotein (LDL) cholesterol levels while increasing high-density lipoprotein (HDL) cholesterol levels. There is compelling level 1 evidence that this reduction of total and LDL cholesterol levels markedly lowers the incidence of secondary cardiovascular events and mortality. There is, however, no direct evidence that lipid control has an effect on the progression of renal artery disease, though one might reasonably suspect that it would.

Statins generally are well tolerated, but on occasion, they may be associated with hepatic toxicity (0.5% to 3% of cases) or myositis. Accordingly, liver function tests should be performed at baseline and again 3 months after the start of therapy. If a threefold or greater increase in aminotransferase levels is noted, the statin should be discontinued, and alternative therapy with another lipid-lowering medication (e.g., a fibrate, a bile acid sequestrant, a cholesterol absorption inhibitor, or nicotinic acid) should be started in conjunction with diet modification.

Muscle injury is uncommon with statin therapy alone: myalgias occur in 2% to 11% of patients, myositis in 0.5%, and rhabdomyolysis in fewer than 0.1%. Myositis associated with statin therapy is treated by switching to another HMG-CoA reductase inhibitor. Routine measurement of serum creatine kinase levels is not recommended, but patients taking statins should be warned about the risk of myositis and weakness and instructed to stop statin therapy if such side effects occur.

Antiplatelet Agents

Antiplatelet therapy has been shown to reduce the risk of secondary events in patients with coronary artery disease and carotid stenosis. The data currently available do not conclusively demonstrate that antiplatelet therapy has a beneficial effect on RAS, but given that RAS is a manifestation of systemic atherosclerosis, antiplatelet therapy appears warranted on the same grounds that statin therapy would be. After endovascular intervention to treat RAS, we typically place patients on ASA, 81 mg/day, and clopidogrel, 75 mg/day, for 4 to 6 weeks while the stent is undergoing endothelialization. After this period, patients are switched to ASA, 325 mg/day. Admittedly, there is no direct evidence supporting this practice in patients with RAS who undergo endovascular intervention; however, data extracted from the coronary stenting literature suggest that such an approach may be reasonable.

ENDOASCULAR AND OPEN SURGICAL THERAPY

Despite the relatively high prevalence of RAS, especially in persons who have atherosclerosis in other vascular beds, there is currently no consensus on diagnosis, therapy, or follow-up. In the absence of well-designed, evidence-based studies, many practitioners have adopted a “find it and fix it” approach to managing RAS. The endovascular and surgical interventions employed to treat RAS are described more fully elsewhere [see 6:22 *Open Procedures for Renovascular Disease* and 6:23 *Endovascular Procedures for Renovascular Disease*]. We ourselves generally take an aggressive stance toward the application of renal artery stenting, especially in patients with evidence of ischemic nephropathy (who presumably would be the patients most likely to benefit from renal revascularization).

It must be admitted, however, that the current evidence for renal artery percutaneous intervention is circumstantial at best. Clearly, there are three possible outcomes associated with renal revascularization. Some patients derive tremendous benefit from the procedure, showing substantial improvements in blood pressure and renal function. Others (a very small subset) experience a rapid decline in renal function, probably resulting from either atheroembolization or CIN associated with the procedure itself. Still others exhibit no changes in renal function, number of antihypertensive medications used, or blood pressure control. Unfortunately, there are, at present, no good methods of reliably predicting which patients will benefit from renal revascularization.

Several uncontrolled reports suggested that hypertension and renal function may improve after successful renal artery stenting. However, three small trials evaluating angioplasty alone (i.e., without stenting)

were unable to demonstrate any beneficial effect on blood pressure.¹⁶⁻¹⁸ Proponents of renal artery intervention have argued that these three trials were flawed by their failure to include stenting and by the fact that blood pressure control may be a poor surrogate clinical end point. These studies were plagued by several other weaknesses as well, including high rates of crossover to angioplasty and marked variations in the medical therapy provided. The inclusion of stenting as a component of endovascular treatment of RAS is now considered the standard of care by many, in that it significantly improves technical success rates and lowers the incidence of restenosis.

Revascularization of RAS with stenting treats the root cause of the neurohormonal activation that leads to end-organ heart and kidney damage; best medical therapy, when adequately carried out, yields substantial reductions in cardiovascular morbidity and mortality in and of itself. Consequently, it is difficult to detect significant differences between best medical therapy alone and best medical therapy plus renal artery stenting. Until sufficient evidence (from adequately powered, well-designed, and unbiased trials) has been accumulated to confirm or rule out such differences, the debate regarding the benefits of percutaneous renal artery revascularization will continue.

To date, no trials comparing best medical therapy with best medical therapy plus angioplasty and stenting have been completed. Currently, however, patients are being recruited into a clinical trial sponsored by the National Heart, Lung, and Blood Institute, which is likely to answer several important questions about the management of RAS that have not been answered by previous studies. This study, known as the Cardiovascular Outcomes in Renal Atherosclerotic Lesions (CORAL) trial, is expected to yield important information about which groups of RAS patients benefit from endovascular intervention. A total of 1,080 patients will be enrolled in the trial and will be randomly assigned to receive either best medical therapy or best medical therapy with angioplasty and stenting. The primary outcome evaluated will be adverse cardiovascular and renal events. Best medical therapy will be provided on the basis of current evidence-based guidelines, which include tight control of blood pressure (< 140/90 mm Hg; < 130/80 mm Hg in patients with diabetes or proteinuria), treatment of hypercholesterolemia (LDL concentration < 100 mg/dl) and diabetes (glycosylated hemoglobin [HbA_{1c}] level < 7 mg/dl), smoking cessation, and antiplatelet therapy (with ASA, clopidogrel, or ticlopidine). All patients will receive an ARB as the first-line antihypertensive agent, and a specific stepwise algorithm will be implemented for patients requiring combination antihypertensive therapy. All patients will undergo diagnostic angiography to assess the severity of their lesions. Patients will be followed for as long as 5 years with an eye to both primary end points (e.g., death, stroke, myocardial infarction, ARF, and dialysis) and secondary end points (e.g., hypertension, medication use, quality of life, and cost). It is expected that enrollment in the CORAL trial will conclude in 2009, though interim data will probably be reported earlier. This important study should make a major contribution to determining the appropriate role of endovascular stenting in the management of RAS.

Discussion

Pathophysiology of Renovascular Hypertension

The seminal studies performed by Goldblatt and associates in the 1930s demonstrated that reduction of renal perfusion can result in sustained elevation of arterial pressures.¹⁹ Later work revealed that the renin-angiotensin-aldosterone system plays an intricate and crit-

ical role in this process. The RAAS maintains vascular tone, water and salt balance, and cardiac function. It works through the sympathetic nervous system and the actions of several hormones to maintain hemodynamic stability. The RAAS is activated through several mechanisms, including hypotension and decreased intravascular

volume. These mechanisms cause decreased renal perfusion and the secretion of renin from the juxtaglomerular apparatus within the kidneys. Renin cleaves angiotensinogen in the liver to form angiotensin I; ACE then transforms angiotensin I into angiotensin II in the lung. Angiotensin II is a potent vasoconstrictor (considerably more potent than epinephrine) and is implicated in end-organ damage to the heart and the kidney.^{20,21} Angiotensin II promotes the release of aldosterone from the adrenal cortex, and this release of aldosterone leads to the reabsorption of sodium in the distal convoluted tubules of the kidney, resulting in increased intravascular volume.

In patients who have unilateral RAS with a normal contralateral kidney, the elevation of blood pressure is renin dependent and is characterized by increased peripheral vascular resistance. Such patients are considered to have volume-independent hypertension, in that the normal contralateral kidney compensates for the unilateral RAS by increasing its excretion of fluid. In patients who have bilateral RAS or unilateral RAS with no contralateral kidney, intravascular volume increases and renin secretion decreases over time. Such patients are considered to have volume-dependent or Goldblatt hypertension.

Ischemic injury to the affected kidney, hypertensive nephrosclerosis of the contralateral kidney, and smooth muscle hypertrophy in the peripheral blood vessels may all contribute to sustained hypertension independently of RAAS activity. In addition, both the sympathetic nervous system and the central nervous system contribute to hypertension associated with RAS.²² Several neuroendocrine systems activated by RAS have also been shown to have deleterious cardiovascular effects. Besides increasing peripheral resistance, angiotensin II is thought to cause smooth muscle hypertrophy (both in peripheral arteries and in cardiac myocytes), plaque rupture, endothelial dysfunction, and inhibition of fibrinolysis.²³⁻²⁵ An elevated angiotensin II level is believed to cause left ventricular hypertrophy (LVH) on occasion, even in cases where blood pressure is well controlled.²⁶ Angiotensin II also interacts with tumor growth factor- β , platelet-derived growth factor, and endothelin, each of which has been implicated in the development of vascular muscle hypertrophy, cardiac myocyte hypertrophy, and renal parenchymal damage. Clearly, RAS and activation of the RAAS have systemic effects that go beyond simply causing hypertension.

22 OPEN PROCEDURES FOR RENOVASCULAR DISEASE

*Christopher J. Godshall, MD, FACS, Racheed J. Ghanami, MD, and Kimberley J. Hansen, MD, FACS**

With the introduction of potent new antihypertensive agents and percutaneous endovascular methods of management, the indication and methods for renovascular intervention have changed. Currently, open surgical repair is commonly reserved for (1) patients who have severe hypertension despite optimal medical therapy, (2) patients in whom percutaneous transluminal renal artery angioplasty (PTRA) fails or who have disease patterns that are not amenable to PTRA, and (3) patients who have renovascular disease associated with excretory renal insufficiency (i.e., ischemic nephropathy).¹

The experience of our center (Wake Forest University School of Medicine) in the management of more than 1,000 patients over a 20-year period indicates that atherosclerotic renovascular disease frequently exists in combination with diffuse extrarenal atherosclerosis and renal insufficiency. In one study, bilateral atherosclerotic renal artery lesions were present in two thirds of patients, and complete renal artery occlusion was present in more than one third.² Although practitioners frequently cite selected data to support a particular management scheme in this setting, the question of what constitutes optimal management of atherosclerotic renovascular disease responsible for either hypertension or renal insufficiency is still unanswerable. To date, no prospective, randomized trials have compared the best medical management with PTRA and with open surgical repair.

Preoperative Evaluation

Evaluation and diagnosis of renovascular hypertension and renovascular renal insufficiency (i.e., ischemic nephropathy) are discussed in more detail elsewhere, as are general issues related to the question of medical versus surgical therapy.^{2,3}

The progressive nature of the atherosclerotic renovascular lesions seen in combination with severe hypertension and the deterioration of renal function seen in selected patients who are managed medically lends support to the idea that renal artery intervention is indicated when either renovascular hypertension or ischemic nephropathy is present. In our view, renal artery intervention is appropriate in patients with severe hypertension and, specifically, in all patients who have severe hypertension in combination with excretory renal insufficiency (i.e., ischemic nephropathy). Open operative management is preferred for children and young adults and for patients with bilateral renovascular disease, especially if renal artery occlusion is present.²

* The authors and editors gratefully acknowledge the contributions of the previous authors, Mathew S. Edwards, MD, and Juan Ayerdi, MD, to the development and writing of this chapter.

Financial disclosure information is located at the end of this chapter before the references.

PTRA is liberally used as an alternative to open renal artery revascularization, but the data currently available suggest that it should be employed selectively. The best results with PTRA alone have been achieved with nonostial atherosclerotic renal artery lesions and medial fibroplasia of the main renal artery. Suboptimal results have been achieved with hypoplastic (i.e., developmental) lesions, fibrodysplasia of the intimal and perimedial variety, ostial atherosclerotic renal artery lesions, and renal artery occlusions. For ostial renal artery atherosclerosis, some surgeons have advocated PTRA with primary endoluminal stenting in an effort to improve results; however, the recovery of renal function after PTRA and primary stenting in this setting have been inferior to those of open operative repair. Consequently, in the majority of cases of bilateral ostial atherosclerosis in combination with renal insufficiency, we advise operative intervention for good-risk patients.

These recommendations are not absolute. Decisions regarding therapy for renovascular disease must be individualized. Factors contributing to the choice of treatment include the expected morbidity and mortality of operative repair and the presence of predictors of death and dialysis dependence at follow-up. In this regard, severe left ventricular systolic and diastolic dysfunction with clinical congestive heart failure, diabetes mellitus, and uncorrectable azotemia have all been shown to be significant and independent predictors of reduced dialysis-free survival.^{2,3}

Operative Planning

Our use of open surgical methods to treat atherosclerotic renovascular disease is based on several guiding principles [see Table 1]. We consider severe hypertension a prerequisite for open operative management and do not perform prophylactic renal artery repair in patients who are not hypertensive. Although we employ renal vein renin assays

Table 1 Recommended Principles for Contemporary Surgical Management of Renovascular Disease¹⁰

Renal artery repair is done on an empirical, but not prophylactic, basis
Complete renal artery repair is done in one operation when feasible; bilateral ex vivo reconstruction may be staged
Direct aortorenal methods of reconstruction are preferred
Nephrectomy is reserved for nonreconstructable disease in a nonfunctioning kidney
Combined aortic reconstruction is limited to clinically significant disease
Intraoperative duplex sonography is performed to assess technical success

to guide management of unilateral lesions in many cases, we typically perform empirical renal artery repair without functional studies when the hypertension is severe or uncontrolled and when renal artery disease is bilateral or involves a solitary kidney. We attempt to correct all hemodynamically significant renovascular disease in a single operation; we perform staged repair only in cases in which the disease necessitates bilateral ex vivo reconstruction. Because the lower limit of renal function retrieval is not known but improved renal function is known to be the strongest predictor of dialysis-free survival, we reserve nephrectomy for patients who have an unreconstructable lesion in a renal artery supplying a nonfunctioning kidney (i.e., a kidney providing less than 10% glomerular filtration on renography).⁴ In the majority of open operative repairs, we employ direct aortorenal reconstruction methods; we seldom use indirect (splanchnorenal) methods because celiac axis stenosis is present in 30 to 40% of patients and bilateral repair is required in more than 50%.² Regardless of the method of reconstruction employed, we perform intraoperative renal duplex sonography as a completion study to look for any technical errors in the repair that might lead to restenosis or occlusion. Failed renal artery repair has been associated with a significant and independent risk of eventual dependence on dialysis.⁵

Operative Technique

Various open surgical techniques are used to correct atherosclerotic renovascular disease; however, no single repair technique is optimal for all renovascular lesions. The best approach to renal artery reconstruction in any given case depends on patient characteristics, the pattern of renal artery disease, and the presence or absence of associated aortic lesions that may have to be corrected simultaneously. The open procedures most commonly performed to treat renovascular disease are (1) aortorenal bypass, (2) renal artery thromboendarterectomy, and (3) renal artery reimplantation. In general, aortorenal bypass is the most versatile of these procedures. Transaortic thromboendarterectomy may be especially useful when ostial atherosclerosis ends within 1 cm of the origin of the renal artery and involves multiple renal arteries. Renal artery reimplantation is often particularly appropriate for the correction of renovascular disease in children and adolescents in that concerns regarding graft material are eliminated.

With all of these reconstruction techniques, multiple small doses of mannitol are administered intravenously during perirenal aortic and renal artery dissection. Mannitol is given both before and after periods of warm renal ischemia up to a total dose of 1 g/kg. During cross-clamping of the aorta and the renal artery, the patient is given heparin, 100 units/kg, to establish systemic anticoagulation. When a purely autogenous reconstruction is performed, antibiotics are unnecessary; however, when a prosthetic graft is employed, administration of a first-generation cephalosporin is begun 2 hours before operation and continued for 24 hours.

AORTORENAL BYPASS

Aortorenal bypass [see Figure 1] may be performed with either an autogenous conduit or a prosthetic graft. If an entirely autogenous repair is possible, we prefer to use a

Figure 1 Aortorenal bypass.⁸ Technique for end-to-side (a, b) and end-to-end (c) aortorenal bypass grafting. The length of arteriotomy is at least three times the diameter of the artery to prevent recurrent anastomotic stenosis. For the anastomosis, 6-0 or 7-0 monofilament polypropylene sutures are used in continuous fashion, under loupe magnification. If the apex sutures are placed too deeply or with excess advancement, stenosis can be created, posing a risk of late graft thrombosis. The dotted lines demonstrate aortotomy and spatulation of the vein. Inset demonstrates final step in spatulation of the vein.

reversed segment of the great saphenous vein as the conduit. If the saphenous vein is inadequate in size (i.e., < 4 mm in diameter) or of inadequate quality, a 6 mm thin-walled polytetrafluoroethylene (PTFE) graft is used instead. In either case, the infrarenal aorta is dissected and clamped proximally and distally, and a longitudinal elliptical opening is created anterolaterally in the aortic wall (e.g., with two or three applications of a 4.0 mm aortic punch). If required, a local endarterectomy at the site of the anastomosis may be performed through this aortotomy.

The proximal and distal anastomoses are then created. Although end-to-side distal renal artery anastomoses were commonly performed at one time, current aortorenal bypass techniques typically employ end-to-end distal renal artery anastomoses. For both the proximal and the distal anastomosis, the length of the arteriotomy should be at least three times the diameter of the smallest conduit, and the ends of the conduit should be widely spatulated to guard against late suture line stenosis. The proximal anastomosis is usually made with a continuous 6-0 monofilament polypropylene suture, and the distal anastomosis is created with a continuous 7-0 monofilament polypropylene suture.

THROMBOENDARTERECTOMY

Thromboendarterectomy of the renal arteries and the perirenal aorta may be performed via either a transrenal or a transaortic approach. When the renal artery atheroma extends 1 cm or less from the ostium and involves both or multiple renal arteries, the transaortic technique [see Figure 2] is especially useful. With both endarterectomy techniques, extensive aortic exposure is required. The aorta proximal to the origin of the superior mesenteric artery (SMA) is exposed and controlled. This exposure is facilitated by partially

Figure 2 Thromboendarterectomy.⁸ Exposure for a longitudinal transaortic endarterectomy is obtained via the standard transperitoneal approach. The duodenum is mobilized from the aorta laterally in the standard fashion; alternatively, for more complete exposure, the ascending colon and the small bowel are mobilized. (a) The dotted line shows the location of the aortotomy. (b) The plaque is transected proximally and distally, the renal arteries are everted, and the atherosclerotic plaque is removed from each renal ostium. The aortotomy is typically closed with a continuous 4-0 or 5-0 polypropylene suture. IMA = inferior mesenteric artery; SMA = superior mesenteric artery.

dividing the aortic crura and controlling the SMA with a Silastic loop.

Currently, the majority of aortorenal endarterectomies are performed through a longitudinal aortotomy extending from a point 2 to 3 cm below the renal arteries to the base of the SMA. A sleeve of aortic atheroma is created and then divided sharply at the base of the SMA proximally and well below the most inferior renal artery distally. After the aortic endarterectomy is completed, an eversion-type endarterectomy is performed for each renal artery. The surgical assistant retracts the anterior lip of the aortic wall and inverts the renal artery into the aorta, and the operating surgeon retracts the renal artery atheroma while gently pushing the remaining renal artery away with a dissector. In this manner, the end point of the endarterectomy can easily be visualized to confirm that the endarterectomy is complete. The endarterectomy site is then irrigated with heparinized saline, and the longitudinal aortotomy is closed with a continuous 4-0 or 5-0 monofilament polypropylene suture.

Both transrenal and transaortic thromboendarterectomy are contraindicated if aneurysmal degeneration of the perirenal aorta is present or if there is transmural calcification at the site of endarterectomy.

RENAL ARTERY REIMPLANTATION

In the course of renal artery exposure, the vessel is dissected from its aortic origin to its primary bifurcation. On occasion, after complete dissection, the vessel is found to have sufficient redundancy to allow tension-free reimplantation into the infrarenal aorta [see Figure 3]. As in a renal artery bypass [see Aortorenal Bypass, above], an elliptical section of the aortic wall is resected, and a widely spatulated aortorenal anastomosis is fashioned.

Although this technique has only limited applicability to the treatment of atherosclerotic renovascular disease in adults, it may be particularly useful in children and young adolescents, who often have congenital or developmental lesions that involve the renal artery orifice. The main advantage of

Figure 3 Renal artery reimplantation.⁹ (a) When the renal artery is redundant and the disease involves the orifice of the renal artery, it is usually possible to reimplant the vessel at a lower level. The dotted lines indicate the location of the aortotomy and the point where the renal artery is divided. (b) An elliptical opening is created in the aortic wall, and a local endarterectomy is done as required. (c) A monofilament suture is placed in the aortic wall. (d) The native renal artery is ligated, proximally spatulated, and reimplanted.

reimplantation is that it obviates concerns regarding the durability of the renal artery conduit.

EX VIVO RENAL ARTERY RECONSTRUCTION

Due to the widespread use of percutaneous techniques for main renal artery pathologies, a significant proportion of open renal artery reconstructions require branch exposure and branch reconstruction. These procedures may require a complex repair, culminating in prolonged renal ischemia. Available data suggest that when more than 40 minutes of warm renal ischemia is required for renal revascularization, measures to protect renal function should be instituted.

Several pharmacologic therapies have been promoted to provide protection during renal ischemia; however, no therapy to date has surpassed hypothermia for protection when renal ischemia exceeds 1 hour. Surface cooling and hypothermic perfusion have been proposed; however, the advantages of each are not well defined. Renal tolerance to ischemia is, in part, related to the duration of ischemia, to the adequacy of collateral circulation, and to the method of vascular control. Unprotected warm renal ischemia is best tolerated when only the renal artery is controlled. Control of both renal artery and vein is associated with greater dysfunction than isolated arterial control, as is intermittent control with repeated renal perfusion.

Numerous methods for renal cooling and hypothermia during branch renal artery repair have been described; however, our preference has been intermittent hypothermic perfusion with topical ice slush. Otherwise, several steps

are common to each branch renal artery reconstruction. To promote renal cortical perfusion, small doses of intravenous mannitol are administered throughout renal artery exposure and reperfusion. Before the division of the renal artery, intravenous heparin (100 units/kg) is administered and monitored as described earlier.

Hypothermia appears to be more important than the composition of perfusate; however, our preference is a perfusate with an intracellular composition of electrolytes. This composition theoretically limits ion exchange and intracellular volume shifts that contribute to organelle dysfunction associated with decreased activity of membrane-bound sodium potassium adenosine triphosphatase. Regardless of whether there is division and reattachment of the renal vein, branch renal artery repairs using cold perfusion preservation are made in an orthotopic fashion, with the kidney returned to the renal fossa rather than autotransplanted into the pelvis.

Several exposures for hypothermic branch renal artery reconstructions are available. When isolated branch renal repair is performed with orthotopic replacement, an extended flank incision is made from the lower rib margin and carried to the posterior axillary line as described earlier. This latter method is our preferred approach for ex vivo reconstruction. The ureter is mobilized to the pelvic brim with a large amount of periureteric soft tissue. An elastic sling is placed around the ureter to control ureteric collaterals and prevent subsequent renal rewarming.⁶

The Gerota fascia is opened with a cruciate incision, the kidney is completely mobilized, and the renal vessels are divided. The kidney is placed in a plastic sling and perfused with a chilled renal preservation solution. Continuous perfusion during the period of total renal ischemia is possible with perfusion pump systems and may be superior for prolonged renal preservation. However, simple intermittent flushing with a chilled preservation solution provides equal protection during the shorter periods (2 to 3 hours) required for ex vivo dissection and branch renal artery reconstructions.⁶ For this technique, we refrigerate the preservative overnight, add additional components immediately before use to make up a liter of solution and hang the chilled (5 to 10°C) solution at a height of at least 2 m. Three to 500 milliliters of solution are flushed through the kidney immediately after its removal from the renal fossa until the venous effluent is clear and all segments of the kidney have blanched. As each anastomosis is completed, the kidney is perfused with an additional 100 to 200 mL of chilled solution. In addition to maintaining satisfactory hypothermia, periodic perfusion demonstrates suture line leaks that are repaired prior to reimplantation. With this technique, renal core temperatures are maintained at 10°C or below throughout the period of reconstruction.

Even though it is an accepted method after ex vivo reconstruction, autotransplantation to the iliac fossa is unnecessary for most ex vivo reconstructions. This technique was adopted from renal transplantation. Reduction in the magnitude of the operative exposure, manual palpation of the transplanted kidney, and ease of removal when treatment of rejection fails are all practical reasons for placing the transplanted kidney into the recipient's iliac fossa. However, none of these advantages apply to the patient requiring autogenous ex vivo reconstruction. Because many ex vivo procedures are performed in relatively young patients, the durability of the operation must be measured in terms of

decades. For this reason, attachment of the kidney to the iliac arterial system within or below sites that are susceptible to subsequent atherosclerosis subjects the repaired vessels to disease that may threaten their long-term patency. Moreover, subsequent management of peripheral vascular disease may be complicated by the presence of the autotransplanted kidney. Finally, if the kidney is replaced in the renal fossa and the renal artery graft is properly attached to the aorta at a proximal infrarenal site, the result should equal that of the standard aortorenal bypass and thus carry a high probability of technical success and long-term durability.

SPLANCHNORENAL BYPASS

Indirect, or splanchnorenal, bypass [see Figure 4 and Figure 5] is an uncommon procedure at our center. In large part, its relative rarity reflects the frequent presence of simultaneous disease of the celiac axis and the frequent need for bilateral renal artery reconstruction in combination with aortic repair. In addition, this approach does not yield long-term patency equivalent to that provided by direct aortorenal reconstruction. Consequently, these indirect bypass techniques are reserved for a selected subgroup of high-risk patients.

Hepatorenal bypass is most frequently performed through a right subcostal incision and splenorenal bypass through a left subcostal incision. In either procedure, the patient is positioned with a roll beneath the ipsilateral flank, with the operating table flexed and the ipsilateral arm padded and tucked to the side. The incision may be extended to the contralateral semilunar line and into the ipsilateral flank as necessary for exposure. In a hepatorenal bypass, a great saphenous vein graft is usually employed, originating from the common hepatic artery and coursing posterior to the portal triad and anterior to the vena cava before the end-to-end renal artery anastomosis [see Figure 4]. A splenorenal bypass may be created either in a similar fashion (i.e., with a great saphenous vein graft) or by anastomosing the transected splenic artery directly to the left renal artery [see Figure 5]. If the latter approach is taken, the collateral circulation to the spleen is sufficient to maintain splenic viability in most cases.

NEPHRECTOMY

In patients with renovascular renal insufficiency or ischemic nephropathy, an incremental increase in excretory

Figure 4 Hepatorenal bypass.⁹ (a) Exposure of the common hepatic artery and the proximal gastroduodenal artery in the hepatoduodenal ligament in preparation for hepatorenal bypass (typically through a right subcostal skin incision). (b, c) The reconstruction is completed by placing a greater saphenous vein interposition graft between the side of the hepatic artery and the distal end of the transected right renal artery.

A splenectomy is not routinely performed.

renal function after operation is the dominant determinant of dialysis-free survival. As noted [see Operative Planning, above], we reserve nephrectomy for patients in whom an unreconstructable renal artery is supplying a nonfunctioning kidney. When the renal artery is occluded, reconstruction is performed if the distal renal artery is normal at the time of surgical exploration. Past recommendations regarding the management of renal artery occlusion have emphasized kidney length, distal renal artery reconstitution, and the appearance of a nephrogram during angiography as criteria for determining whether reconstruction is indicated. Our practice, however, has been to perform renal artery reconstruction whenever a normal distal renal artery is demonstrated. In a study employing this strategy, we reported retrieval of renal function in 60% of occluded renal arteries that underwent operative repair.⁴

INTRAOPERATIVE RENAL DUPLEX ULTRASONOGRAPHY

The surgeon's technique plays a dominant role in determining patency after renal artery reconstruction. To look for technical errors at the time of operation, we employ intraoperative renal duplex ultrasonography. A 10.0/5.0 mHz compact linear array probe with Doppler color-flow capability is placed within a sterile sheath that has a latex tip containing sterile gel. The operative field is flooded with warm saline solution, and B-scan images are obtained from the sites of aortic control and of renal artery repair. All defects noted on

the B-scan images are then examined in both longitudinal and transverse projections. Doppler samples are obtained proximal and distal to the lesions to determine their hemodynamic significance.⁷ In 249 consecutive renal artery repairs with anatomic follow-up, 10% had a focal increase in peak systolic velocities consistent with residual stenosis.² Each defect was revised immediately, and in each case, a significant defect was found. At 12 months after operation, primary patency of the renal reconstruction was observed in 97% of repairs. This product-limit estimate of patency is stable up to 10 years after operation.

Outcome Evaluation

Surgical repair of atherosclerotic renovascular disease can be accomplished with a high rate of success and sustained long-term patency. With proper patient selection, the majority of patients demonstrate beneficial blood pressure response and renal function response, albeit with perioperative mortality and morbidity that vary according to the complexity of the procedure.

In a 2002 report, we reviewed our center's experience with 500 consecutive patients who underwent open surgical repair for treatment of atherosclerotic renovascular disease between January 1987 and December 1999.² These patients included 254 women and 246 men, with a mean age of 65 ± 9 years. Each patient had severe hypertension. The mean

preoperative blood pressure for the group was $200 \pm 35/104 \pm 21$ mm Hg. Most of the patients had diffuse extrarenal atherosclerosis. Eighty-one percent had at least one manifestation of cardiac disease, 34% had a history of significant cerebrovascular disease, and 78% were considered to have at least mild renal insufficiency, as evidenced by a serum creatinine concentration of 1.3 mg/dL or greater. Ischemic nephropathy was seen in 244 patients (49%), including 40 patients who were dependent on dialysis before operation.

Angiographic evaluation demonstrated the presence of bilateral renal artery disease in 60% of these atherosclerotic patients. The renal artery lesion was considered ostial in 97% of cases, and 16% of renal arteries were completely occluded. A total of 720 renal artery reconstructions were performed [see Table 2]. Aortorenal bypass was performed in two thirds of the repairs, and two thirds of these bypasses were done with venous grafts. Thromboendarterectomy was performed in almost one third of the cases. Renal artery reimplantation was performed in 56 instances and splanchnorenal bypass in only 13 instances. Although there were 124 renal artery occlusions, only 56 of these were treated by means of nephrectomy.

Twenty-three patients (4.6%) died in the hospital or within 30 days of renal reconstruction. Mortality varied significantly with the magnitude of procedure. Mortality after isolated renal artery repair was substantially lower than mortality after combined aortic and bilateral renal artery repair (0.8% versus 6.9%). Moreover, perioperative mortality demonstrated significant and independent associations with advanced age and clinical congestive heart failure. The estimated primary patency rate for all 720 renal artery reconstructions was 97% at the 8-year follow-up.

HYPERTENSION RESPONSE

Early blood pressure response was estimated on the basis of ambulatory blood pressure values and medication requirements determined at least 1 month after operative repair. Among surgical survivors, 12% were considered cured, 73% were considered improved, and 15% were considered failed [see Table 3].

RENAL FUNCTION RESPONSE

A significant change in excretory renal function was defined as a change of at least 20% in the estimated glomerular filtration rate (EGFR), measured at least 3 weeks

Table 3 Results of Operative Treatment of Atherosclerotic Renovascular Disease among 477 Surgical Survivors²

after repair. Of patients with preoperative ischemic nephropathy, 58% showed improvements in renal function, including 30 patients removed from dialysis dependence [see Table 3]. In contrast to previous reports that suggested the existence of a lower limit of renal dysfunction beyond which recovery could not be observed, the percentage of patients who showed improvement rose with increasing preoperative serum creatinine concentration. Overall, 75% of dialysis-dependent patients were permanently removed from dialysis after renal artery repair. In addition, the site of disease and the extent of repair were found to influence increases in the EGFR. Although each subgroup of patients who underwent operation demonstrated some improvement in renal function, the greatest incremental increase in the EGFR was observed in those who underwent bilateral renal reconstruction for significant bilateral disease.^{3,6}

RELATIONSHIP OF HYPERTENSION RESPONSE AND RENAL FUNCTION RESPONSE TO DIALYSIS-FREE SURVIVAL

At a mean follow-up of 56 months, 171 patient deaths had occurred. When outcomes were considered in terms of the blood pressure response to operative intervention, only hypertension cured was found to be significantly and independently associated with survival or dialysis dependence: patients whose hypertension was cured experienced improved dialysis-free survival [see Figure 6]. In contrast, all outcome categories for the renal function response influenced both survival and eventual dialysis dependence. Patients with improved renal function experienced a significant increase in dialysis-free survival [see Figure 7].² For patients whose renal function remained unchanged after operation, however, the risk of eventual dialysis dependence and death was equivalent to that of patients whose renal function worsened after surgery. Although renal function that is unchanged after intervention is frequently described as “stabilized” or “preserved,” our experience suggests that patients with ischemic nephropathy and atherosclerotic renovascular disease whose renal function is unchanged postoperatively remain at increased risk for eventual dialysis dependence and death. Whether similar associations exist for patients treated by means of catheter-based

23 ENDOVASCULAR PROCEDURES FOR RENOVASCULAR DISEASE

Matthew S. Edwards, MD, FACS, William B. Newton III, MD, and Kimberley J. Hansen, MD, FACS

The treatment of renovascular disease is currently in a state of evolution. Open surgical revascularization remains the gold standard, having demonstrated its durability and efficacy in treating renovascular hypertension and ischemic nephropathy; however, it is associated with substantial morbidity and mortality, even when performed at centers with extensive experience.¹⁻⁴ As a result, endovascular techniques for renal revascularization, including percutaneous transluminal angioplasty with or without endoluminal stent placement (PTAS), have emerged as the preferred option for revascularization of occlusive renal artery lesions. Compared with conventional open surgical revascularization, these endovascular techniques offer a number of potential benefits (e.g., decreased morbidity, lower mortality, shorter recovery times, and reduced hospital resource use); however, they also possess certain potential drawbacks (e.g., reduced effectiveness and decreased durability).

Predictably, controversy persists regarding the appropriate application of surgical and endovascular therapies to the treatment of renovascular disease, with proponents of each modality citing selected literature to support their position. In what follows, we review key technical aspects of endovascular renal revascularization and summarize the current data on technical results, clinical outcomes, and associated complications.

Preoperative Evaluation

The general principles of preoperative evaluation and patient selection for persons being considered for renal revascularization, whether open or endovascular, are addressed in more detail elsewhere. As a rule, our group reserves renal artery PTAS for patients with renal artery stenosis in combination with severe hypertension with or without renal insufficiency.

CONTRAST ARTERIOGRAPHY

Despite advances in diagnostic imaging that allows noninvasive identification of patients with renovascular disease,⁵⁻⁹ the formulation of an endovascular therapeutic plan depends on visualization of the renal artery anatomy by means of angiography. Accordingly, contrast angiography of the renal arteries should be considered an integral component of the therapeutic armamentarium for clinically significant renal artery lesions.

CONTRAST-INDUCED NEPHROPATHY

Patients with renovascular disease have a high prevalence of associated medical comorbidities (e.g., diabetes mellitus,

congestive heart failure, chronic renal insufficiency, and diuretic-induced intravascular volume depletion). These conditions may necessitate alterations in the usual routines for patient preparation and use of iodinated contrast agents. Such agents are known to be capable of impairing excretory renal function,¹⁰ sometimes permanently. The risk of this complication is highest in persons with preexisting dehydration,¹¹ renal insufficiency,¹²⁻¹⁴ or diabetes mellitus,¹⁵⁻¹⁷ especially the juvenile variety. Administration of large volumes of iodinated contrast material^{18,19} and use of high-osmolality agents¹⁵⁻¹⁷ may also increase the risk of renal function impairment. Several reports, however, have suggested that periprocedural administration of acetylcysteine,^{20,21} sodium bicarbonate hydration,²² and vitamin C can lower the risk of renal function impairment after angiography.

In light of available evidence, our current policy is to prepare all patients for aortorenal arteriography with saline hydration (limited in patients with significant heart failure) and periprocedural administration of acetylcysteine, along with limited use of sodium bicarbonate in patients who have preexisting renal insufficiency. Furthermore, we routinely select low-osmolality iodinated contrast agents in these patients and limit the volumes infused. In patients with moderate to severe preexisting renal insufficiency, carbon dioxide^{23,24} may also be employed as an intra-arterial contrast agent to reduce or eliminate the use of iodinated contrast material. Our practice with such patients is to use carbon dioxide for initial localization [see Figure 1a] and selective cannulation [see Figure 1b] of the renal artery and then to employ an iodinated contrast agent in small volumes for definitive planning and performance of the required intervention.

TECHNICAL CONSIDERATIONS

Femoral artery access is the most versatile and lowest risk option. For nonselective renal arteriography, either femoral artery provides adequate access. For selective renal cannulation, however, it is generally better to use the femoral artery contralateral to the renal artery for intervention; this approach takes advantage of the tendency of the catheter to track preferentially toward the contralateral aortic wall and facilitates cannulation of the renal ostia.

If the patient has downsloping renal arteries or if femoral access is not advisable, brachial artery access is a useful alternative. It is preferable to access the left brachial artery so as not to cross the origin of the right common carotid artery. Access may be established by means of either percutaneous or open techniques. The risk of complications is higher with percutaneous brachial artery access, and the maximum permissible sheath and catheter sizes are smaller.²⁵ Accordingly, we generally use an open approach for brachial artery access, with puncture, cannulation, and suture closure carried out under direct vision.

Financial disclosure information is located at the end of this chapter before the references.

Figure 1 (a) Bilateral high-grade renal artery stenosis visualized by using carbon dioxide angiography to localize the renal ostia. (b) Selective right renal artery cannulation with placement of a 6 French left internal mammary artery guide catheter and selective renal arteriography using hand-injected half-strength iso-osmolar contrast material.

PROJECTIONS

Aortography and selective renal angiography with multiple projections are necessary for full radiographic evaluation of the renal arteries and the juxtarenal aorta. Initial anteroposterior (AP) images of the visceral aorta are obtained by delivering power contrast injections through a flush catheter with multiple side holes positioned at the L1-L2 interspace. These initial AP views provide an overview of the renal artery and the perivisceral aortic anatomy [see Figure 2]. Additional nonselective images of the renal arteries should be obtained by moving the catheter to a location below the origin of the superior mesenteric artery to prevent contrast opacification of the visceral vessels, which could obscure the anatomic details of the renal arteries.

The renal arteries usually arise from the anterolateral right or the posterolateral left aspect of the aorta. As a result, lesions within the renal ostia often are not seen or appear insignificant on AP aortograms. Oblique aortography and oblique selective renal arteriography project these portions of the vessel in profile and thus are often better at identifying any renal ostial lesions present. As a rule, the single most useful projection for visualizing the renal ostia is a 15° to 20° left anterior oblique view, although other oblique views may also be necessary.^{26,27} Axial images of the renal origins (i.e., computed tomographic scans) may allow estimation of the necessary degree of obliquity and permit the use of smaller amounts of iodinated contrast material and lower doses of ionizing radiation [see Figure 3].

For full delineation of lesions within the body of the renal artery, selective arteriographic views may be required. Selective cannulation is usually performed with a configured

Figure 2 An anteroposterior aortogram is obtained by delivering a power injection of iso-osmolar iodinated contrast material through a 5 French pigtail catheter positioned at the L1-L2 interspace.

Figure 3 Axial computed tomographic scan of the renal artery origins allows estimation of the degree of obliquity required for optimal imaging of the renal ostia.

catheter (e.g., a cobra catheter, a Sos catheter, or a renal double-curve catheter). The varying configurations of available catheters offer specific advantages in particular anatomic situations. Before selective renal artery cannulation, we administer heparin intravenously. Once the guide wire has been gently advanced into the renal artery ostia, contrast material is injected by hand to confirm intraluminal placement. Selective images are then obtained with low-volume power injection or hand injection (our preference) of contrast material [see Figure 4]. The proximal third of the left

Figure 4 Selective arteriography of the right renal artery using hand-injected iso-osmolar contrast material through a complexly curved Simmons catheter.

renal artery usually courses anteriorly, the middle third transversely, and the distal third posteriorly; the right renal artery generally pursues a more consistent posterior course. For full delineation of lesions in the various segments, oblique and cranial-caudal projections may be necessary.

ADJUNCTIVE MEASURES

Renal artery angiography affords the surgeon the opportunity to employ other measures to characterize a renal artery lesion. For example, the hemodynamic effects of an angiographic stenosis or interaction can be assessed by making direct pressure measurements proximal and distal to the lesion. In general, we consider any pressure gradient greater than 12 mm Hg to be indicative of hemodynamically significant renovascular disease. Additional anatomic information can be obtained by means of intravascular ultrasonography of the renal artery, which can provide detailed information on plaque morphology, vessel size, and potential dissection flaps to complement the data obtained through arteriography.^{28,29}

ANGIOGRAPHIC CHARACTERISTICS

Atherosclerotic renovascular disease

Atherosclerosis of the renal artery accounts for approximately 85% of all renovascular lesions. Elderly persons with multiple comorbid medical conditions and manifestations of atherosclerosis are most frequently affected.^{30–33} Atherosclerotic renal lesions represent a continuation of a process that begins in the aorta and spills over into the origin of the renal vessels [see Figure 5]. These lesions are characterized by an eccentric, irregular narrowing of the ostium and the proximal portion of the renal artery [see Figure 6]. In the majority of cases, the lesions are limited to the ostia and the proximal renal artery.³⁴ The aortic origin of the lesion has important implications for treatment. Placement of an endovascular stent into the proximal renal artery, without covering the aortic origin of the plaque, may result in residual or recurrent disease. Occlusions of the renal artery are also common in patients with clinically significant disease [see Figure 7] and frequently occur in the setting of contralateral renal artery stenosis.^{2,3}

Fibromuscular dysplasia

Fibromuscular dysplasia (FMD) is a term used to describe a group of histologically distinct pathologic conditions of

Figure 5 An aortic endarterectomy specimen demonstrates the pathologic basis of atherosclerotic renovascular disease.

Figure 6 A magnified preintervention aortogram demonstrates ostial right renal artery atherosclerotic stenosis.

the arterial wall that most commonly affect the main renal artery and its branches. FMD of the renal artery, with resultant renal artery stenosis, is responsible for approximately 10 to 15% of treated cases of renovascular hypertension.³⁵ The lesions are categorized according to the layer of the

Figure 7 An aortogram demonstrates right renal artery stenosis and left renal artery occlusion with distal renal artery reconstitution.

arterial wall involved—hence the terms medial fibroplasia, perimedial dysplasia, and intimal fibroplasia. Medial fibroplasia is the most common variant, representing 85% of recognized cases. It is encountered almost exclusively in women, most commonly in the third or fourth decade of life.^{35,36} The arteriographic pattern most frequently associated with medial fibroplasia resembles a string of beads [see Figure 8], an appearance created by weblike stenotic areas with intervening areas of poststenotic dilatation. These lesions are frequently bilateral and can be associated with renal artery aneurysm or dissection.³⁷ Medial fibroplasia of the main renal artery is among the lesions most amenable to endovascular treatment. In our view, however, the presence of branch vessel disease or aneurysms precludes safe treatment.

Perimedial dysplasia accounts for approximately 15% of cases of FMD and is most commonly manifested by the appearance of multiple irregular stenoses without microaneurysms.³⁶ Intimal fibroplasia is the least common variant of FMD, representing fewer than 5% of recognized cases, and the typical lesions are smooth concentric stenoses.^{35,36} In general, perimedial dysplasia and intimal fibroplasia tend to respond less well to endovascular treatment than the medial fibroplasia variety.

Procedural Planning

PATIENT PREPARATION

Recently, the use of statins has been associated with a significant and independent decrease in restenosis. Corriere and colleagues reported that patients not receiving statin therapy have a threefold increase in estimated restenosis over time.³⁸ Consequently, statin therapy is initiated prior to intervention. Patient preparation for renal artery PTAS is similar to that routinely carried out for diagnostic arteriography. Oral intake of food and liquid is stopped at midnight the evening before the procedure. Warfarin is discontinued at least 4 days beforehand; aspirin and clopidogrel are continued. Intravenous fluids and acetylcysteine

Figure 8 A selective right renal arteriogram demonstrates findings indicative of medial fibroplasia.

are administered the evening before the procedure, with care taken to avoid fluid overload in patients with impaired cardiac function. Routine medications, with the exception of angiotensin-converting enzyme inhibitors and angiotensin receptor antagonists, are taken on the morning of the procedure with a sip of water. A first-generation cephalosporin is administered intravenously 30 minutes before the procedure unless the patient is allergic.

After the intervention, the patient is observed in the hospital overnight to check for access-site problems and severe alterations in blood pressure. Acetylcysteine is continued throughout the hospital stay, and oral administration of clopidogrel is initiated the evening after the procedure. The patient continues to take clopidogrel for at least 30 days after revascularization and remains on aspirin therapy indefinitely.

CORRELATION OF DIAGNOSTIC IMAGES WITH CLINICAL FINDINGS

Once the diagnostic portion of the procedure is completed, the images obtained are closely examined and correlated with the patient's clinical presentation. Intra-arterial pressure measurements are occasionally misleading in renal vessels. Because most renal arteries are approximately 5 to 6 mm in diameter, a stenotic lesion that causes a greater than 60% reduction in the luminal diameter leaves only 2.0 to 2.5 mm of patent lumen. A 4 or 5 French diagnostic catheter may completely occlude this narrowed lumen, thus resulting in an inaccurately low pressure measurement distal to the stenosis. Accordingly, it is our practice to assess the anatomic arteriographic information in light of the functional significance of the lesion as determined by either renal vein renin assays or duplex ultrasonography.

MATERIALS AND INSTRUMENTS

The materials commonly used for renal artery PTAS at our center include various guide wires, catheters, sheaths, balloons, and stents [see Table 1]. The basic principles underlying the use of these devices are outlined more fully elsewhere [search ACS Surgery for further information on endovascular surgery].

Procedural Technique

STEP 1: SECURE RENAL ARTERY ACCESS FOR THERAPEUTIC INTERVENTION

Once the decision for endovascular intervention is made, the patient is systemically heparinized, and the 5 French diagnostic catheter and the introducer sheath are exchanged over a 0.035 in. guide wire so that an access platform can be established that will provide secure renal artery access for the therapeutic intervention.

Most angioplasty and stenting devices in current use will pass through a 6 French lumen. Access options include guide sheaths and guide catheters. Common to both of these options is the provision of a long mechanical support segment for guide-wire placement that affords direct access to the renal artery for easy passage of therapeutic devices to the target lesion [see Figure 9]. Such systems vary in shape and diameter and come in multiple configurations to facilitate renal artery access in different situations.

After the tip of the guide catheter is positioned at or within the renal artery orifice, guide-wire access across the lesion is obtained. For all subsequent manipulations, the sheath or the guide catheter should not be advanced beyond the orifice, because the nontapered tip may injure the vessel. Depending on the type, severity, and location of the lesion, a 0.35, 0.18, or 0.14 in. guide wire with a floppy radiopaque tip is chosen. The smaller guide-wire systems appear to have inherent advantages, in terms of ability to cross tighter stenoses, limitation of renal artery trauma, and liberation of emboli, but whether these apparent advantages are real remains to be proved. Once the guide wire is in place, the access platform is secured and remains in place until the intervention and any postintervention imaging are complete.

STEP 2: TRANSLUMINAL ANGIOPLASTY

With the guide wire secured distal to the lesion, therapeutic intervention may proceed. Both coaxial systems (in which the entire catheter is exchanged over the wire, so that an assistant is required to control the wire during intervention and catheter exchange) and monorail or rapid-exchange systems (in which only the distal portion of the catheter is over the wire, so that a single operator can control the wire during intervention and catheter exchange) are available for renal artery intervention.

Regardless of the system chosen, the principles of intervention remain the same. Transluminal angioplasty of the renal artery may be performed either as the sole therapy for a renal artery lesion or as a means of predilating a lesion so that an endoluminal stent can be placed. Angioplasty may also be employed to treat recurrent renal artery stenoses after surgical or endovascular therapy. Angioplasty is an effective stand-alone therapy in most cases of main renal artery disease (FMD and nonostial atherosclerosis) but is frequently ineffective for atherosclerotic ostial and proximal renal artery disease.

The angioplasty balloon size is chosen on the basis of quantitative angiographic images. Direct cut-film images with ball-bearing or marker-catheter reference points may be used, as may the quantitative software packages available on most contemporary digital angiographic systems. In general, the angioplasty balloon should be slightly larger than the adjacent normal artery for primary treatment and somewhat smaller for predilation of a stenotic lesion. For predilation before endoluminal stent placement, we usually employ a 3 × 20 mm low-profile angioplasty balloon. This choice tends to make the stent passage less traumatic and helps in estimating the stent diameter and length required.

During inflation of the angioplasty balloon, the aortic origin of most ostial plaques is indicated by the appearance of a visible "waist," and the image can be centered over a bony landmark to facilitate subsequent stent placement. It is not unusual for the patient to experience some discomfort during balloon inflation. This discomfort should resolve quickly when the balloon is deflated; if it does not, renal artery trauma should be suspected. It is our practice to inflate the balloon slowly to its fully inflated profile at the rated nominal pressure and then maintain inflation for 30 to 45 seconds before deflation.

Table 1 Standard Equipment for Renal PTAS

Device Category	Type	Proprietary Name	Length	Diameter
Guide wires	Initial	Starter 3 mm J	180 cm	0.035 in.
	Selective	Magic Torque	180 cm	0.035 in.
		Platinum Plus, V-18 Transend, GuardWire	145–180 cm 165–200 cm	0.018 in. 0.014 in.
Catheters	Flush angiography	Pigtail	70 cm	5 Fr
	Selective: diagnostic	Cobra C1 or C2	65 cm	5 Fr
		Contra 2	65 cm	5 Fr
		VS-1 or Sos	65 cm	5 Fr
		Simmons	65 cm	5 Fr
	Selective: guide	Renal Double Curve	55 cm	6 Fr
		LIMA	55 cm	6 Fr
		JR 4	55 cm	6 Fr
		Hockey Stick	55 cm	6 Fr
	Pressure measuring	Straight Glide, Export	90 cm	4 Fr
Sheaths	Initial access		10 cm	4–5 Fr
	Therapeutic access		10 cm	6 Fr
	Selective: guide	Pinnacle Destination	45 cm	6 Fr
		Flexor Check Flow ANL2	45 cm	6 Fr
Angioplasty balloons	Predilation	Savoy, Gazelle, Aviator, Symmetry	1.5–2.0 cm balloon 75–90 cm shaft	3 mm balloon 5 Fr sheath
	Therapeutic	Savoy, Gazelle, Aviator, Symmetry	1.5–2.0 cm balloon 75–90 cm shaft	4–7 mm balloon 5 Fr sheath
Stents*	Balloon-expandable	Genesis, Express	12–29 mm stent	5–7 mm stent
			75–90 cm shaft	6 Fr sheath

PTAS = percutaneous transluminal angioplasty with or without endoluminal stent placement.

*None of these stents are approved by the Food and Drug Administration for use in renal arteries.

Once the balloon has been completely deflated, it is removed, and selective angiography is repeated to assess the response of the lesion to angioplasty and check for complications. Guide-wire access must be maintained until the end of the procedure so that complications or unsatisfactory results (e.g., dissection or residual stenosis) can be addressed.

Figure 9 (a) A guide catheter inserted through a short 6 French arterial sheath. (b) A diagnostic catheter inserted through a guide sheath.

STEP 3: ENDOLUMINAL STENTING

Endovascular stent placement may be performed either as a primary procedure or as a secondary procedure in response to suboptimal results from angioplasty. Most FMD lesions and nonostial atherosclerotic lesions respond well to angioplasty alone. Secondary stent placement should, however, be considered for nonostial lesions that do not respond appropriately to angioplasty. Secondary stent placement is typically performed to address elastic recoil, residual stenosis (> 30%), pressure gradients (> 10 mm Hg), and myointimal flaps or dissections. Either balloon-expandable or, less commonly, self-expanding stents may be employed in the renal artery. Typically, balloon-expandable stents have greater radial strength and can be placed more precisely, whereas self-expanding stents are more flexible and conform more readily to the shape of the lumen. We employ balloon-expandable stents primarily in the treatment of ostial atherosclerotic lesions, where their advantages are particularly useful.

In general, the technical aspects of stent placement parallel those of transluminal angioplasty. Frequent hand injections of small amounts of contrast material through the guide sheath or catheter are employed to guide the stent into position across the lesion before deployment [see Figure 10]. After the stent has been deployed, completion angiography is performed while guide-wire access to the renal artery is

Figure 10 (a) The orifice of a right renal artery with high-grade ostial stenosis is selected with a 5 French cobra catheter, and the lesion is crossed with a 0.014 in. guide wire. (b) A balloon-mounted stent is positioned across the renal artery stenosis with the help of intermittent contrast injections and bony landmarks. (c) A fully expanded stent is positioned in the renal artery.

maintained. This is accomplished by hand injection of contrast through the guide sheath or catheter. For the treatment of ostial or proximal renal artery lesions, it is preferable to position the stent with 1 to 2 mm extension into the aorta. Frequent hand injection of contrast material through the guide sheath allows precise placement of the stent and helps prevent misdeployment. If the stent is placed too far into the artery, the true renal orifice is not supported, and there is a greater chance of residual or recurrent disease.^{39–43} Such recurrent disease often does not respond to further endovascular attempts; accordingly, it is advisable to use the shortest possible stent that will adequately support the lesion. In addition, a stent that extends well out into the distal renal artery can make later surgical options more difficult⁴⁴ and typically carries a higher failure rate.

A balloon-expandable stent is deployed by inflating the angioplasty balloon on which it is mounted. In the past, these stents had to be crimped and hand-mounted on the angioplasty balloon, which made their delivery somewhat insecure. Currently available stents, however, come securely premounted on low-profile delivery systems capable of passing across most lesions with minimal or no predilation. We deploy these stents with 1 to 2 mm extension into the aorta, guided by anatomic information provided by previous positioning over bony landmarks. Self-expanding stents, although not commonly applied to the treatment of renovascular disease, can also be employed in this setting. These devices are deployed by retracting an outer membrane of the delivery device to expose the stent. Care must be taken

during deployment to ensure that foreshortening of the stent does not compromise coverage of the lesion.

After a stent is deployed, there may be residual narrow areas within the stent that necessitate balloon dilatation. These areas may be visible on fluoroscopic evaluation of the stent or detected during postdeployment selective renal angiography.

After all therapeutic measures have been completed, the technical result is assessed and undetected defects are sought by means of repeat pressure-gradient measurements, intravascular ultrasonography, or both. When a satisfactory result is obtained, the guide wire and the sheath are removed and hemostasis is secured. Although it is possible to perform bilateral renal interventions in a single procedure, we prefer, when possible, to stage these interventions so as to minimize contrast loads.

Postprocedural Care

Longitudinal follow-up of all patients undergoing renal revascularization is mandatory to check for recurrent disease, contralateral disease, and deterioration of clinical benefit, as well as other preventable cardiovascular and peripheral vascular conditions. Our current approach to follow-up entails clinical visits at 1, 3, 6, 9, 12, 18, and 24 months after renal artery PTAS, with renal duplex ultrasonography, blood pressure measurement, and serum creatinine measurement at each visit. After 24 months, this intensive early follow-up is relaxed to a yearly visit schedule if no conditions necessitating shorter visit intervals have been identified.

Recurrent disease after renal stenting is a significant concern, and disease that recurs within the stent itself can be a particularly challenging problem [see Figure 11a]. Because most such recurrences are related to intimal hyperplasia, repeat balloon angioplasty generally does little to improve the situation. Initial dilatation with a Cutting Balloon (Boston Scientific, Natick, MA) is extremely useful for releasing the fibrous scar tissue of the restenotic lesion and allowing subsequent dilatation to a larger diameter with a conventional angioplasty balloon. The Cutting Balloon consists of a noncompliant balloon with three or four atherotomes (microsurgical blades) mounted longitudinally on its outer surface [see Figure 11b]. When the device is inflated, the atherotomes score the intimal hyperplasia within the stent; the balloon is then rotated and reinflated to score the lesion in multiple planes. To date, this technique has been used primarily in coronary arteries, but it has also been applied to the treatment of renal artery in-stent restenosis.⁴⁵ After the lesion has been scored, a larger balloon is inserted and inflated to redilate the lesion [see Figure 11c].

Complications

Potential complications include access-site complications (e.g., hematoma, pseudoaneurysm, retroperitoneal hemorrhage, arteriovenous fistula, and closure-device infection), contrast-mediated allergic reactions or nephrotoxicity, atheroembolism, and direct renovascular trauma. In a meta-analysis published in 2000, the reported complication rate after renal PTAS ranged from 0 to 40% (mean rate 11%).³⁴

Figure 11 (a) High-grade recurrent in-stent restenosis of the right renal artery. (b) The Cutting Balloon is useful in dealing with such lesions. (c) Dilation with a 4 × 15 mm Cutting Balloon is followed by dilation with a standard 6 × 20 mm angioplasty balloon, and a completion angiogram is obtained.

The most frequently reported complications were hematomas at arterial access sites. Severe complications occurred in 9% of patients and included renal failure, segmental renal infarction, perinephric hematoma, and renal artery thrombosis. The mean mortality was 1%.

A large single-center retrospective review of complications after endovascular treatment with renal artery stenting reported similar results.⁴⁶ Major complications occurred after 15 of 179 procedures (8.4%) and included renal infarction, permanently increased serum creatinine concentration, dialysis dependence, blood transfusion, surgical intervention, and deep vein thrombosis. There was no apparent association between pretreatment patient characteristics and the subsequent incidence of major complications. Two patients (1.1%) died within 30 days after the procedure.

Outcome Evaluation

To be considered successful, renal artery revascularization should (1) improve quality of life, (2) reduce the incidence of adverse cardiovascular disease events, (3) slow or halt the progression of chronic renal insufficiency, (4) lower the incidence of dialysis-dependent renal failure, or (5) improve overall survival. Unfortunately, few studies have addressed these clinical outcome measures. Consequently, the outcome of renal revascularization is currently assessed on the basis of (1) the extent to which the procedure is anatomically or technically successful and (2) the degree to which the procedure alleviates or cures associated hypertension and ischemic nephropathy. Technical success and the response of hypertension or renal dysfunction to therapy are assumed to be the mechanisms by which the five important clinical outcomes listed are achieved.

Interpretation of the results of renal artery PTAS as reported in the current literature is challenging. Despite the publication of hundreds of reports on this procedure, it remains unclear how renal artery PTAS compares with surgical renal revascularization and whether renal artery PTAS conveys any meaningful benefit to patients beyond what can be achieved with medical therapy alone. These shortcomings in our understanding of renal artery PTAS (and of surgical renal revascularization, for that matter) stem largely from the lack of well-designed clinical trials investigating these questions. Such trials will ultimately be necessary to establish the utility and safety of renal artery PTAS in the treatment of renovascular disease. Until such trials are performed, interpretation of the existing literature is a valuable guide for prudent application of renal artery PTAS.

HYPERTENSION RESPONSE

Three pre-2000 randomized, controlled studies have compared endovascular therapy with medical treatment of renovascular hypertension [see Table 2]. These studies provide the best available data on the efficacy of endovascular therapy for managing hypertension but are limited in their contemporary utility in that they all investigated the use of renal artery angioplasty without primary stent placement and use of antiquated medical management. The first study involved 49 patients with unilateral renal artery stenosis who were randomly assigned to either angioplasty or best medical hypertension treatment.⁴⁷ The angioplasty group demonstrated no statistically significant decrease in blood pressure; however, it did demonstrate improvement in hypertension control, as evidenced by a significant reduction in the amount of antihypertensive medications required. The second study, reported by the Scottish and Newcastle Renal Artery Stenosis Collaborative Group, involved 55 patients who were randomly assigned to either angioplasty or best medical antihypertensive therapy.⁴⁸ Patients with both unilateral and bilateral renal artery stenosis were included in this study. There was a modest improvement in blood pressure control in the angioplasty group, but this benefit was confined to those patients who had bilateral disease. None of the patients were cured of their hypertension. The third study was performed by the Dutch Renal Artery Stenosis Intervention Cooperative Study Group.⁴⁹ A total of 106 patients were randomly assigned to either renal artery angioplasty or best medical therapy for renovascular hypertension. At 12 months, there was no significant reduction in either systolic or diastolic blood pressure, although multiple treatment crossovers occurred that might have skewed the results toward the best medical therapy arm. The authors concluded that angioplasty had little advantage over antihypertensive therapy in the treatment of renovascular hypertension.

Table 3 summarizes the hypertensive response in 1,377 patients from various published reports treated with renal artery angioplasty and stenting since 2000. The overall hypertension cure rate was 4%, with a range of 0 to 8%. Fifty-four percent of the patients had improved blood pressure control, with a range of 0 to 91%. However, it is also important to note that the periprocedural morbidity was 6.6% and the periprocedural mortality was 1% for these patients.

Table 2 Summary of Trials Included in Meta-Analysis

<i>Trial</i>	<i>Patients (n)</i>	<i>Unilateral or Bilateral Disease</i>	<i>Randomized Treatment</i>	<i>Duration of Follow-up</i>	<i>Main Endpoints</i>
Webster et al. ⁴⁸	55	Unilateral and bilateral, but two groups analysed separately	Angioplasty vs medical management	Patients reviewed at end of 4-week run-in period (baseline) then at 1, 3 and 6 months, then at 6-monthly intervals	Primary: BP and SCr at 6 months and the change in these from baseline Secondary: major events
Plouin et al. ⁴⁷	49	Unilateral only	Angioplasty (with or without stent insertion) vs medical management	Patients reviewed at end of 2–6 week run-in period (baseline) then at 6 months	Primary: BP at termination* and the change from baseline Secondary: treatment score and incidence of complications
van Jaarsveld et al. ⁴⁹	106	Unilateral and bilateral	Angioplasty vs medical management	Patients reviewed every 1–3 months, and always at 3 and 12 months	Primary: BP at 3 and 12 months Secondary: treatment score, SCr, SCr clearance, patency, and incidence of complications

BP = blood pressure; SCr = serum creatinine concentration.

* Termination defined as 6 months after randomization or earlier in cases of refractory hypertension (diastolic BP > 14 mmHg despite maximal tolerated antihypertensive regimen). In such cases, BP, treatment score and SCr were determined prior to renal arteriograph.

To date, only one prospective, randomized, controlled study has compared endovascular treatment with surgical revascularization for the treatment of renovascular hypertension.⁵⁰ In this report, 58 patients with renovascular hypertension were randomly assigned to either surgical revascularization or angioplasty. In both groups, hypertension was cured or improved in approximately 90% of patients. However, more than half of the patients in whom angioplasty failed were switched to the surgical arm for revascularization. On the basis of these results, the authors recommended angioplasty as the treatment of choice for selected renovascular lesions contributing to renovascular hypertension, with aggressive follow-up and repeat intervention (endovascular and surgical) carried out as needed. Investigators have reported that the beneficial blood pressure response seen after open surgical repair for failed angioplasty may be less than that seen in patients who undergo primary surgical repair without previous endovascular treatment.⁴⁴ Moreover, a previous endovascular procedure may make open surgical repair technically more demanding, especially if an endoluminal stent is present.

Two large contemporary clinical trials of renal artery stent placement and best medical therapy versus best medical therapy alone have also been recently completed. The Angioplasty and Stenting for Renal Artery Lesions (ASTRAL) trial commenced patient recruitment in September 2000.⁵¹ The trial randomized patients with significant anatomic atherosclerotic renovascular disease to either percutaneous transluminal renal angioplasty with stenting (PTRAS) with best medical management (e.g., statins, antiplatelet, antihypertensive therapy) or optimal medical management alone. The primary end point was the rate of change in renal function over time. Secondary end points included blood pressure control, adverse heart and vascular events, and mortality.

The first published report of the ASTRAL trial results is available.⁵¹ A total of 806 patients (403 randomized to each group) were enrolled. The trial included a mean follow-up of 33.6 months, with all surviving patients having completed a minimum of 12 months of follow-up. At baseline, trial group demographics were virtually identical for the two groups. The average degree of stenosis for the most severe renal artery lesion was 76%. Sixty percent of patients had renal artery stenosis exceeding 70%. Mean blood pressures were reported as 149/46 and 152/76 mm Hg in the PTRAS and medically managed groups, respectively. Patients averaged 2.8 antihypertensive medications in both groups.

The ASTRAL trial demonstrated no difference in blood pressure, renal function, adverse renal events, vascular events, or mortality between the two groups. In the PTRAS group, 6.8% of subjects suffered significant complications, including renal artery perforation, thrombosis, embolization, and significant renal insufficiency. Ignoring complications requiring admission, another 20% of PTRAS patients experienced less serious complications, consisting primarily of groin hematoma and mild renal insufficiency. Although the ASTRAL trial represents the largest published prospective, randomized clinical trial to date to examine the role of PTRAS, the trial has received substantial criticism. Patients were excluded from randomization if their physician felt it likely that they would benefit from PTRAS. As a consequence, it may be argued that those patients who would likely benefit from PTRAS were systematically omitted. In addition, of 403 patients randomized to PTRAS, 40% had stenosis between 50 and 70%. Moreover, pressure gradients across the stenosis were not measured before or after therapy. Finally, only 359 of 403 patients randomized to PTRAS underwent the procedure, whereas 24 of 403 patients assigned to medical management underwent intervention.

Table 3 Renal Artery Revascularization with Angioplasty and Stenting*

Reference	Year	Patients	Bilateral Treatment (%)	Preprocedural Renal Dysfunction (%)	Renal Function Response (%)			Hypertension Response (%)			Periprecedural Mortality (%)	Periprecedural Morbidity (%)
					Improved	Unchanged	Worsened	Cured	Improved	Failed		
Burket et al ⁶⁶	2000	126	NR	29	43	24	56	8	NR	NR	2	4
Lederman et al ⁶⁷	2001	265	41	37	7.5	78	14	NR	70	30	< 1	2
Bush et al ⁶⁸	2001	73	16	68	23	51	26	6	89	5	1.4	9
Rocha-Singh et al ⁴⁰	2002	51	55	100	77	18	5	NR	91	9	0	14
Gill and Fowler ⁴¹	2003	100	26	75	31	38	31	4	79	17	2	18
Zeller et al ⁶⁹	2004	456	NR	52	34	39	27	NR	46	54	< 1	NR
Nolan et al ⁷⁰	2005	82	NR	59	23	53	24	0	81	0	0	7
Kayshap et al ⁷¹	2007	125	36	100	42	23	25	0	0	0	1.6	6
Corriere et al ⁵³	2008	99	11	75	28	65	7	1	21	78	0	5.5
Mean% [†]			31	55	28	38	31	4	54	29	1	6.6

NR = not reported.

* Series selected based on publication in 2000 or later, use of angioplasty and stenting, and inclusion of more than 50 patients, and categorical reporting of renal function and/or hypertension responses.

[†] Weighted mean based on number of patients with reported data categorized according to column; references where data was not reported or categorical response categories were combined were not included in calculation.

However, when the trial results are examined on a “per protocol” basis, there was no apparent benefit for PTRAS.

Data from the other outstanding large prospective randomized clinical trial, the Cardiovascular Outcomes in Renal Atherosclerotic Lesions (CORAL) trial are eagerly awaited as that trial does not have many of the previously mentioned limitations.

RENAL FUNCTION RESPONSE

Several factors hinder accurate assessment of the effect of renal artery PTAS on renal function. To date, no prospective, controlled studies have compared renal function responses after medical, surgical, and endovascular treatment of renal artery stenosis. Most observational series report results from a diverse group of patients whose baseline renal function and subsequent responses to treatment vary widely. Interpretation of the existing renal function response data is further complicated by the limitation of serum creatinine measurement (the most commonly employed indicator of renal function in these studies) to detect changes in renal function, especially in patients with serum creatinine levels lower than 1.2 mg/dL.

These limitations notwithstanding, a number of reports published between 2000 and 2008 provided useful data on renal function response after renal artery PTAS, expressed in terms of a change (or lack of change) in serum creatinine concentration [see Table 3]. With improvement defined as a 20% or greater decrease in serum creatinine concentration, response rates ranging from 7.5 to 77% were observed (mean 28%). These results are very similar to those reported in the 2000 meta-analysis (range 0 to 50%; mean response rate

30%).³⁴ A number of authorities also make use of the concept of “stabilized” renal function, defined as a less than 20% change in serum creatinine concentration. By this definition, renal function was stabilized in the majority of patients included in the studies published between 2000 and 2008 (range 18 to 78%; mean response rate 38%) [see Table 3]. Again, these results are very similar to those reported in a meta-analysis from 2000 (range 0 to 64%; mean response rate 38%).³⁴ A significant percentage of treated patients (range 5 to 56%; mean 31%) also experienced post-PTAS worsening of renal function.

Although all investigators agree that worsened post-PTAS renal function represents a treatment failure, it is less clear whether an unchanged serum creatinine concentration should be considered beneficial to the patient. In one study, 88% of patients treated for renal dysfunction exhibited improved or stabilized serum creatinine levels after angioplasty, stenting, or both.⁵² Only 25% of patients, however, showed sustained responses over a 5-year follow-up period; the remainder demonstrated continuing deterioration of renal function. These results contrast sharply with those of reports addressing open surgical treatment of renal dysfunction, which documented durable improvement or stabilization rates of 85 to 93% and 5-year dialysis-free survival rates of 50 to 55%.²⁻⁴ Furthermore, patients with ischemic nephropathy whose renal function did not change after open surgical revascularization had increased rates of death and dialysis dependence during follow-up that were similar to those noted in patients with decreased renal function after revascularization.^{2,3} These findings suggest that improved postprocedural renal function may be the most important

surrogate outcome marker for predicting improved survival and dialysis independence; however, function unchanged is not consistent with “preserved” or “stable” renal function.

LONG-TERM COMPLICATIONS

Complications may also develop in a delayed manner. The principal long-term complications include restenosis of the renal artery and inadequate durability of clinical benefit. Restenosis is a common occurrence with all catheter-based methods of revascularization. According to the meta-analysis cited earlier,³⁴ restenosis complicates 11 to 42% (mean 26%) of renal artery angioplasties and 12 to 23% (mean 17%) of renal artery stent procedures including a restenosis rate in excess of 50% at 2 years in our experience. Restenosis may or may not be clinically significant.⁵³ The decision whether to treat restenotic lesions should be made on the basis of the specific physiologic or clinical response to the primary procedure.

The beneficial clinical responses noted after renal artery PTAS frequently are not durable. In two studies that reported on 222 individuals undergoing renal artery PTAS, the investigators found that the clinical response, especially the renal function response, was transient.^{52,54} Overall, at 5 years, 50 to 70% of patients exhibiting a positive hypertension response and fewer than 50% of those exhibiting a positive renal function response (defined as improvement or stabilization) retained any benefit. This deterioration of clinical benefit occurred even though a patent renal artery was maintained in all cases. Such results stand in stark contrast to the documented durability of the clinical response after surgical revascularization and underscore the need for close lifelong follow-up of all patients undergoing renal revascularization.¹⁻⁴

OUTCOMES AFTER RENAL ARTERY PTAS FOR FMD

Patients with FMD respond to renal artery PTAS much differently from those with renal artery atherosclerosis. FMD is most commonly manifested as medial fibroplasia in a young woman. In general, balloon angioplasty appears to be an acceptable treatment for adult patients with such lesions, and this approach yields excellent technical success rates, good clinical benefit, and low morbidity. In a study addressing 85 renal artery stenoses in 66 FMD patients, hypertension was cured or improved in 98% of patients after renal angioplasty, and all patients with elevated creatinine levels exhibited improved or stabilized renal function.⁵⁵ Another study, involving a series of older FMD patients (mean age 59 years) with long-standing hypertension (mean duration 13 years), a similar blood pressure response was noted.⁵⁶ At follow-up more than 3 years later, hypertension was cured in 14% of patients and improved in 74%.

Both studies supported the general consensus that medial fibroplasia of the main renal artery can be adequately treated by means of primary angioplasty, with stent placement reserved for technical complications. Furthermore, it appeared that a beneficial clinical response was seen after endovascular intervention and that this response was more pronounced in younger patients with a shorter duration of hypertension. There is reason to believe that improvements in our ability to select patients most likely to benefit from treatment,^{48,57-61} as well as the emergence of technical

developments aimed at preventing procedure-related embolization⁶²⁻⁶⁴ and long-term restenosis,⁶⁵ may be within reach. Such advances, if realized, may further narrow the gap between the clinical results of surgical renal revascularization and those of its endovascular counterpart and may improve the marginal benefit and safety of renal artery PTAS.

Financial Disclosures: None Reported

24 RAYNAUD PHENOMENON

Tina R. Desai, MD, FACS, and Timothy Wu, MD

Raynaud phenomenon is an episodic, exaggerated vascular response to cold or emotional stimuli, typically involving the fingers. The classic triphasic color change, first described by Maurice Raynaud in 1862, consists of initial pallor (secondary to vasospasm), followed first by cyanosis (from deoxygenation of the static blood) and then by rubor (as blood flow to the digits is restored and reactive hyperemia ensues).¹ This classic manifestation of Raynaud phenomenon occurs in as many as two thirds of affected patients; however, less common variants of the phenomenon (e.g., pallor followed by cyanosis alone and pallor followed by rubor alone) also exist.

Raynaud phenomenon occurs throughout the world. Overall, it tends to be more common in colder climates. In warmer areas of the United States and Spain, the prevalence ranges from 3 to 5%, whereas in cooler areas, the prevalence ranges from 15 to 20%.²⁻⁴ In a study of the African-American population, the prevalence was 3%.⁵

Classification

Raynaud phenomenon is generally classified as either primary or secondary. Primary Raynaud phenomenon occurs as an isolated finding in an otherwise healthy individual; secondary Raynaud phenomenon is caused by an associated disease (in most cases, an autoimmune disease) or by identifiable environmental or chemical exposure [see Table 1].⁶ The two types are distinguished from each other on the basis of clinical criteria, and the distinction has significant prognostic implications.

With primary Raynaud phenomenon, the typical age at onset is 15 to 30 years, symptoms are generally symmetrical and less severe, patients are more likely to be female, and multiple family members may be affected.⁷ With secondary Raynaud phenomenon, the typical age at onset is older, symptoms are usually more severe, and a systemic inflammatory disorder is commonly involved. In fact, Raynaud phenomenon is a prominent component of many autoimmune disorders, occurring in 90% of patients with scleroderma, 10 to 45% of patients with systemic lupus erythematosus (SLE), one third of patients with Sjögren syndrome, 20% of patients with dermatomyositis or polymyositis, and 10 to 20% of patients with rheumatoid arthritis.⁸ In 0 to 13% of patients who present with primary Raynaud phenomenon, an identifiable connective tissue disorder develops within a few years after presentation.^{9,10} The best predictors of transition to such a disorder are (1) serologic findings that are positive for auto-antibody and (2) suggestive physical findings (e.g., abnormal nailfold capillary patterns, cutaneous telangiectasias, puffy fingers, and sclerodactyly).^{6,10}

Table 1 Conditions Associated with Raynaud Phenomenon²¹

Rheumatologic diseases
Systemic sclerosis syndrome (scleroderma)
Systemic lupus erythematosus
Dermatomyositis or polymyositis
Rheumatoid arthritis
Takayasu arteritis
Giant cell arteritis
Thromboangiitis obliterans
Primary biliary cirrhosis
Mechanical injury
Vibration (hand/arm vibration syndrome)
Frostbite
Recurrent trauma or injury to large vessels
Crutch pressure
Thoracic outlet syndrome
Arterial diseases
Brachiocephalic atherosclerosis
Vasospastic disorders
Migraine or vascular headache
Prinzmetal angina
Endocrine disorders
Carcinoid syndrome
Pheochromocytoma
Hypothyroidism
Malignant diseases
Ovarian cancer
Angiocentric lymphoma
Abnormal blood elements
Cryoglobulins
Cold agglutinins
Paraproteinemia
Polycythemia
Infections
Parvovirus B19
<i>Helicobacter pylori</i>
Chemicals or drugs
Bleomycin, vinblastine
Polyvinyl chloride
Beta blockers
Ergots (e.g., methysergide)
Interferon alfa, beta
Tegafur

Clinical Evaluation and Investigative Studies

CHARACTERISTIC FINDINGS

Exacerbation of Raynaud phenomenon typically occurs after direct exposure of an extremity to cold temperatures [see *Sidebar Pathophysiology of Raynaud Phenomenon*], but an attack may also be elicited by generalized cooling of the entire body. In addition, attacks may be precipitated by any

Pathophysiology of Raynaud Phenomenon

Blood flow to the skin is regulated by a complex interaction between the endothelium, vascular smooth muscle, circulating hormones, and neural plexus. Patients with Raynaud phenomenon demonstrate an exaggerated vasomotor response to otherwise benign stimuli, notably cold exposure. Normally, on exposure to cold, blood flow to the skin is reduced in an effort to preserve core temperature. This natural response is mediated primarily by the sympathetic nervous system via the neurotransmitter norepinephrine, which causes contraction of vascular smooth muscle in the cutaneous arterial beds. This cold-induced vasoconstriction of cutaneous vascular smooth muscle appears to be mediated specifically by the α_2 receptor.⁴⁵

It has been suggested that the cold-induced vasoconstriction seen in primary Raynaud phenomenon is the result of exaggerated activity of the α_2 receptors. This suggestion was supported by the results of experiments that blocked the cold-induced vasoconstriction in primary Raynaud phenomenon by delivering α_2 receptor antagonists locally.⁴⁶ The mechanism of this Raynaud-specific hyperactive response has not been fully elucidated, although there is evidence to indicate that the response may, in part, be attributable to increased activity in the protein tyrosine kinase signal transduction pathway.⁴⁷ Endothelial derangements may also contribute to the pathogenesis of primary Raynaud phenomenon through increased plasma concentrations of endothelin and decreased levels of nitric oxide.^{48,49}

In secondary Raynaud phenomenon, it is generally accepted that vascular damage from the underlying disease (especially in the case of scleroderma) is responsible for the disruption of normal vasomotor homeostasis. Activated or damaged endothelial cells exacerbate vasospasm and further damage perfusion by mediating the proliferation and contraction of smooth muscle cells; enhancement of procoagulant activity and reduction of fibrinolysis promote the formation of intravascular microthrombi, and the release of chemotactic and adhesion factors activates local inflammatory processes.²¹

stimulation of the sympathetic nervous system, especially at times of emotional stress.

As a rule, Raynaud phenomenon is more likely to affect the hands than the feet. It is characterized by the sudden occurrence of cold digits in association with sharply demarcated pale skin—the so-called ischemic phase. Eventually, the skin may become cyanotic. Subsequently, rapid restoration of blood flow to the digits results in reactive hyperemia—the reperfusion phase. Attacks typically start in a single digit and spread symmetrically to other digits, eventually involving both hands. Other sites may be involved as well—notably, the ears, the nose, the nipples, the face, and the knees. Ischemic attacks may be accompanied by mottling of the skin on the arms and legs. During the ischemic phase, patients may complain of paresthesias and clumsiness in the involved extremities. In the most severe cases of secondary Raynaud phenomenon, critical ischemia may cause painful digital ulceration.

Raynaud phenomenon should be differentiated from simple “cold hands” (a more common and benign condition). In patients with Raynaud phenomenon, cold hands occur in conjunction with clearly distinguished skin-color changes. Moreover, recovery takes longer than it does in patients who merely have cold hands. The guidelines for diagnosing Raynaud phenomenon are based on a history of color change on exposure to cold or other stimuli. A history of repeated episodes of biphasic skin-color change on exposure to cold is indicative of Raynaud phenomenon. A history of uniphasic skin-color change with paresthesias on exposure to cold is suggestive. In the absence of any skin-color change, Raynaud phenomenon is ruled out.¹¹ Generally, additional diagnostic tests are unnecessary; however, both evaluation of digital pressure response to cooling and laser Doppler assessment of skin perfusion pressure have been employed in this setting. The Nielsen technique¹² is performed with a blood pressure cuff at the proximal phalanx and inflated above the patient’s systolic blood pressure. An arterial opening pressure is determined on deflation of the blood pressure cuff. Temperature differences to the finger can be induced with a second cuff of water around the proximal finger, lowering the temperature as needed, precipitating a Raynaud attack. This is detected by Doppler flow meter or a zero systolic digital pressure

as determined by a transducer. The temperature at which the Raynaud attack is precipitated is known as the arterial closing temperature. Laser Doppler assessment of skin perfusion pressure may be capable of distinguishing between normal control subjects, persons with primary Raynaud phenomenon, and persons with secondary Raynaud phenomenon.^{13–15}

Raynaud phenomenon should also be differentiated from carpal tunnel syndrome and other neuropathies, which may cause cold sensitivity but do not induce the skin-color changes characteristic of Raynaud phenomenon. Patients who have asymmetrical, persistent, or positional symptoms should undergo a full evaluation for possible large vessel occlusive disease, embolism, or thoracic outlet compression, any of which might lead to hand-color changes. Raynaud phenomenon may also be a reflection of a more generalized vasospastic disorder (e.g., migraine headache or Prinzmetal angina).^{16,17}

HISTORY AND PHYSICAL EXAMINATION

Once a diagnosis of Raynaud phenomenon has been established—or, at least, strongly suspected—a thorough history and physical examination can help distinguish between primary and secondary forms of the condition. The presence of specific symptoms of connective tissue disease (particularly arthralgia, myalgia, and dry mucous membranes), extended exposure to vibrating machinery, or antecedent use of certain medications is suggestive of secondary Raynaud phenomenon. The earliest specific diagnostic criteria for primary Raynaud phenomenon were described by Allen and Brown in 1932.¹⁸ More current criteria take advantage of modern diagnostic tools and serologic testing. Primary Raynaud phenomenon is suspected when attacks are symmetrical and episodic, when the history and the physical examination reveal no evidence of tissue gangrene or a possible underlying causative condition, when antinuclear antibody titers and erythrocyte sedimentation rates are normal, and when nailfold capillary examination yields unremarkable results.¹⁹

TESTING FOR SUSPECTED SECONDARY RAYNAUD PHENOMENON

If secondary Raynaud phenomenon is suspected on the basis of the history and the physical examination, more

specific testing is appropriate. A particularly helpful test is nailfold capillaroscopy. The bases of the fingernails of the fourth and fifth digits are examined with a handheld ophthalmoscope set to 10 to 40 diopters after a drop of immersion oil is placed on each nailfold. The normal vascular pattern, seen in healthy control subjects and patients with primary Raynaud phenomenon, consists of delicate “hairpin” capillary loops. However, the pattern seen in patients with Raynaud phenomenon secondary to an underlying cause (e.g., scleroderma, dermatomyositis, or undifferentiated connective tissue disease) often includes enlarged capillary loops, with evidence of angiogenesis, architectural derangements, and areas of decreased vascularity.²⁰ Serologic markers provide additional support for the diagnosis of secondary Raynaud phenomenon: the anti-Smith antibody is specific for SLE, and the antitopoisomerase and anti-RNA polymerase antibodies are highly specific for scleroderma-spectrum disorders. Among experts, there is little doubt that patients with Raynaud phenomenon who test positive for autoantibodies are at higher risk for the eventual development of a connective tissue disease.²¹

Koenig and colleagues prospectively studied 586 patients with Raynaud phenomenon without known connective tissue disease.²² In patients with one or more antibodies (antitopoisomerase, anti-RNA polymerase) noted on serologic testing or with abnormal nailfold capillaroscopy, the incidence of diffuse systemic sclerosis was 47%. Those patients with both an antibody and abnormal capillaroscopy had an incidence of systemic sclerosis of about 80%. The combination of both serology and nailfold capillaroscopy offers more information on the risk of systemic sclerosis than either test alone.

Management

Management of Raynaud phenomenon generally consists of lifestyle modification and medical treatment, with surgical options limited to severe or refractory cases. Nonpharmacologic treatment generally suffices for primary Raynaud phenomenon but is often inadequate for management of secondary Raynaud phenomenon, which is usually more severe. Mild forms of Raynaud phenomenon are managed with lifestyle modification, including maintenance of total body warmth (as well as warmth of hands and fingers), avoidance of cold and emotional stress, cessation of smoking, discontinuance of the use of vibrating tools, and avoidance of vasoconstricting substances (e.g., caffeine, cocaine, beta blockers, and decongestants). Biofeedback training has also been shown to be of some utility in reducing symptoms of Raynaud phenomenon, although several studies have questioned its value, especially in comparison to that of medical management.^{23,24}

Calcium channel blockers are the vasodilators most commonly used to treat Raynaud phenomenon and are the first choice for medical treatment after failure of nonmedical treatment. Nifedipine, diltiazem, felodipine, and amlodipine are all effective, although they tend to be more effective in patients with the primary form of the condition than in those with the secondary form. One meta-analysis found short-acting nifedipine, 10 to 20 mg three or four times a day, to be moderately effective at reducing symptoms in patients with Raynaud phenomenon and scleroderma.²⁵ A large clinical study found sustained-release nifedipine to be useful as well.²³

Another recent meta-analysis of trials involving patients with primary Raynaud phenomenon found that calcium channel blockers reduced the severity of attacks by 33% and the frequency of attacks was reduced by 2.8 to 5.0 times per week.²⁶

Other vasodilators have also been shown to be effective. In one study, losartan, an angiotensin receptor blocker, proved to be more effective than nifedipine in reducing the frequency and severity of episodes of both primary and secondary Raynaud phenomenon.²⁷ Topical nitrates provide a degree of benefit as well.²¹ Because serotonin may be partially involved in the pathogenesis of Raynaud phenomenon, a number of studies have focused on the use of serotonin reuptake inhibitors and serotonin receptor antagonists.²⁸ In a small open-label trial that included both patients with primary Raynaud phenomenon and patients with the secondary form of the condition, fluoxetine was more effective than nifedipine in reducing the severity and frequency of attacks over a 6-week period; the effect was most pronounced in female patients and in patients with primary Raynaud phenomenon.²⁹ In another study, ketanserin, a selective serotonin receptor antagonist that is no longer available in the United States, significantly reduced the number of attacks over a 3-month period.³⁰ Intravenous prostaglandins have also been used with success. In one report, iloprost, given as a 5-day infusion, was beneficial in severe cases of Raynaud phenomenon, mitigating symptoms and enhancing the healing of ischemic ulcers³¹; unfortunately, iloprost is also unavailable in the United States. Of the intravenous prostaglandins currently available in the United States, alprostadil (prostaglandin E₁ [PGE₁]) and epoprostenol (PGI₂) have achieved, at best, mixed results,^{32,33} whereas prazosin has been employed with some success against primary and secondary Raynaud phenomenon (although its effectiveness seems to be limited in patients with scleroderma).³⁴

There has been growing interest in the role that phosphodiesterase inhibitors play in the management of Raynaud phenomenon. The most studied to date has been sildenafil. In a study by Fries and colleagues of 20 randomly assigned patients with Raynaud phenomenon, 50 mg of twice-daily sildenafil or a placebo was given, with significant improvement in the attack rate, duration, and objective measures of nailfold capillary blood flow in the sildenafil group.³⁵ A confounding factor in their study, however, is the fact that patients were able to clearly distinguish sildenafil from the placebo based on the pill's physical characteristics. Zamiri and colleagues, however, found no difference in the number of attacks or nailfold capillary blood flow in their randomized, double-blind, placebo-controlled study of 20 patients in sildenafil and placebo groups.³⁶ The data on sildenafil in Raynaud phenomenon are far from conclusive, and further study to delineate its role is required prior to recommending its use in treatment.

Some authors have advocated low-dose aspirin therapy for Raynaud phenomenon, but, to date, trials of antiplatelet therapy have yielded disappointing results.³¹ In a placebo-controlled, randomized trial published in 2003, cilostazol increased blood vessel diameter in patients with primary and secondary Raynaud phenomenon but did not bring about any improvement in symptoms.³⁷ In smaller studies, some success

was achieved with tissue plasminogen activator and with low-molecular-weight heparin; however, these agents were found to carry significant bleeding risks and thus have not been widely accepted for treatment of Raynaud phenomenon.^{31,38}

For refractory, severe Raynaud phenomenon, surgical management, most often involving some form of sympathectomy, is recommended. Both central and distal sympathectomy have been employed for this purpose; initial success rates are good, but there is a high incidence of recurrent symptoms.

For many years, open cervicothoracic sympathectomy was commonly performed for symptomatic treatment of Raynaud phenomenon (which was thought to result from an overactive sympathetic response), but the results were mixed.^{39,40} The open form of the procedure was associated with substantial morbidity and frequent recurrence of symptoms, and, as a result, it has now been largely abandoned. Some surgeons have advocated performing thoroscopic sympathectomy to treat severe Raynaud phenomenon that is refractory to medical management, but the benefits and durability of this approach have not been established. In this procedure, the ipsilateral pleural space is approached thoroscopically, with the patient under general anesthesia. The sympathetic chain is identified as it courses down the ribs near the costovertebral junction, and the second through fourth thoracic sympathetic ganglia lying between the ribs are cauterized. Bilateral sympathectomy may be performed in a sequential fashion during the same operation. Approximately 90% of

patients experience immediate relief of symptoms after thoroscopic sympathectomy, but the majority also experience recurrence of symptoms.^{41,42} Proponents of this procedure argue that these recurrent symptoms are not as severe as the original preoperative symptoms and that patients who undergo the operation for the treatment of ulceration exhibit continued long-term healing. Nonetheless, in our view, it is advisable to reserve thoroscopic sympathectomy for selected cases of Raynaud phenomenon that are refractory to medical management.

At present, localized digital sympathectomy using microsurgical techniques is generally preferred to proximal sympathectomy for treatment of nonhealing ulcerations in patients with severe, refractory Raynaud phenomenon.⁴³ This procedure involves stripping the adventitia, along with digital sympathetic fibers, from the involved digital arteries, with the patient under either regional or general anesthesia. In one small study of seven patients, it was suggested that this digital sympathectomy could be extended to include the palmar arch, the radial and ulnar arteries proximal to the wrist, and the nerve of Henle, which is responsible for the sympathetic innervation of the distal ulnar artery.⁴⁴ The investigators found that by 1.5 years after adventitial stripping of the proximal radial and ulnar arteries with resection of the nerve of Henle, all ischemic ulcerations had resolved.

Financial Disclosures: None Reported.

25 SCLEROTHERAPY

William R. Finkelmeier, MD, FACS

Sclerotherapy involves the injection of a caustic solution (a sclerosant) into an abnormal vein so as to cause localized destruction of the venous intima and obliteration of the vessel. It is not a new technique, having been practiced since the early 20th century, but it has evolved significantly over the past 50 years.¹ Improvements in the technology used (e.g., hypodermic syringes, fine needles, sclerosants, compression technique, and duplex ultrasonography) have greatly enhanced the results achievable with sclerotherapy. To ensure optimal results, it is essential to have a thorough knowledge not only of the technique but also of the indications, expected outcomes, and possible complications associated with the procedure.

Sclerotherapy is primarily used to treat small varicose veins, reticular veins, and spider veins. The prevalence of varicose and spider veins is well documented: they affect millions of people in the United States alone.¹ The incidence is two to three times higher in women than in men and increases with age. The precise etiology of varicose veins and spider veins is unknown. Heredity, pregnancy, female sex, obesity, an occupation that requires long periods of standing, and a low-fiber diet have been implicated as causative factors. The choice of treatment method for varicose veins and spider veins must be individualized for each patient. Although sclerotherapy is only one of a number of techniques available for treatment, it is an important therapeutic tool and a key component of a vascular surgeon's armamentarium.

Preoperative Evaluation

Proper evaluation of the patient before sclerotherapy is the most important step in achieving successful results. Such an evaluation should include a thorough clinical arterial and venous examination. Close attention should be paid to the size, location, and distribution of vessels; these variables are critical for determining the appropriate treatment. Sclerotherapy failures are often attributable to improper patient selection. Any patient who is believed to have axial reflux or whose clinical complaints far exceed the findings from physical examination should undergo venous duplex ultrasonography.

Venous duplex ultrasonography has revolutionized the treatment of varicose and spider veins. It is reproducible and noninvasive and can objectively identify areas of reflux in the great and small saphenous systems, as well as detect pathologic conditions in the deep venous system and incompetent perforating vessels.

Patients with axial reflux or reflux from the great or small saphenous junction documented by venous duplex ultrasonography are best managed by means of surgical correction of the reflux rather than primary treatment with sclerotherapy. In a 1993 randomized study, ligation and stripping were compared with compression sclerotherapy in 164 patients who had symptomatic primary varicose veins.² After 5 years, 74% of the patients treated with sclerotherapy were considered to have had treatment failures, compared with only 10% of the patients treated surgically. In a 1991 trial, real-time color duplex ultrasonography was used to evaluate 89 limbs in 55 patients who had previously undergone sclerotherapy of the great saphenous vein.³ Obliteration of the great saphenous vein was noted in only 20% of the injected limbs and in only 6% of the limbs below a refluxing junction. These poor results from sclerotherapy were confirmed in a subsequent study.⁴ The superiority of surgical treatment was also demonstrated in a randomized 10-year study comparing surgery with sclerotherapy alone.⁵

Ultrasound-guided sclerotherapy has also been advocated. The advantages of this approach are that it allows much higher concentrations of the sclerosant solution and permits direct visualization of the injections. Reported recurrence rates, although better than with liquid sclerotherapy, are still quite high: 22.8% at 1 year and 27.2% at 2 years.^{6,7} A number of authors have advocated ultrasound-guided foam sclerotherapy for patients with axial reflux.^{8,9} Myers and colleagues reported just over 50% primary success rate with ultrasound-guided foam sclerotherapy of the saphenous vein at 3 years.¹⁰ The unknown longevity of the results achieved with this technique is still in question, and further studies (including randomized trials) are needed for validation. In addition, the number of early failures compared with surgery and ablation make it difficult to recommend this as the treatment of choice. A 2008 article by Gonzalez-Zeh and colleagues comparing endovenous laser ablation to echocardiography-guide foam sclerotherapy showed at 1 year a 93.4% occlusion of the great saphenous vein versus 77.4% with foam.¹¹

Given the available data, my preferred approach is to treat the axial reflux in the great and/or small saphenous veins as indicated by duplex ultrasonography before sclerotherapy. The choice of endovenous ablation versus open surgery depends on the size of the vessels and the presence of large tortuous branches of the saphenofemoral junction. Large tertiary varicosities are best treated with hook phlebectomy at the time of the primary ablative procedure. Patients who do not have axial reflux and whose vessels are less than 6 mm in diameter can

be treated successfully with sclerotherapy alone. Varicose veins more than 6 mm in diameter without axial reflux are best treated surgically by means of phlebectomy by ambulatory hook phlebectomy. The cosmetic results are far better and the recovery time is much shorter with the surgical option.

Operative Planning

PATIENT PREPARATION

Before undergoing sclerotherapy, the patient should receive a thorough explanation of the procedure, including the possible risks and complications [see Table 1]. He or she should be informed about the expected outcomes and the length of time needed for healing. In particular, it should be emphasized that multiple treatments are usually necessary to eliminate varicosities. Most patients can expect to undergo four or five treatments in a 6-month period. Time and patience are essential for achieving an optimal outcome.

Because sclerotherapy without axial reflux is primarily cosmetic and therefore rarely reimbursable, it is important to have a clear understanding regarding costs. A good-faith estimate of the cost per procedure should be provided to the patient before treatment is initiated. It is advisable to have the patient sign a copy of this estimate so that there is no subsequent misunderstanding about the costs to be incurred during the course of therapy.

To reduce bruising, aspirin and antiplatelet agents should be avoided for 10 days before treatment. On the day of the procedure, the patient should be asked to refrain from applying lotion to the legs so that the tape applied after treatment will adhere better to the skin [see Table 2]. The patient should

sign and date an informed consent form. Once informed consent is obtained, photographs of the areas to be treated should be taken. The digital photography should be standardized as much as possible with respect to lighting and background. The problem areas are photographed again after treatment, and additional pictures are obtained during subsequent treatments to document progress. The aim is to give patients a reliable means of objectively comparing the legs' appearance before and after sclerotherapy [see Figure 1, Figure 2, and Figure 3]. Such photographs often reassure patients that significant cosmetic improvement has been achieved and encourage them to continue treatments.

MATERIALS

Sclerosants cause thrombosis and subsequent fibrosis when injected into a blood vessel. An ideal sclerosant would exert this effect reliably while also being inexpensive, widely available, approved by the Food and Drug Administration (FDA), and nontoxic. In addition, it would be painless on injection and would not cause hyperpigmentation or ulceration with extravasation. Unfortunately, this ideal sclerosant does not exist. All of the solutions currently available have disadvantages.

Sclerosants may be classified into two main categories: osmotic agents and detergents. Hypertonic saline (HS) and chromated glycerin (CG) are the most widely used osmotic agents. HS, approved by the FDA as an abortifacient, is commonly employed to treat superficial telangiectasias. HS in a 23.4% concentration damages the endothelial cells of the vessel walls through hyperosmolarity-induced dehydration. Such damage leads to thrombosis and fibrin deposition.

Table 1 Complications of Sclerotherapy

Complication	Comment
Common	
Itching	Usually mild; lasts for 1–2 days
Hyperpigmentation	Occurs in about 20–30% of patients treated; usually fades in a couple of weeks but may take several months to a year to resolve totally; lasts longer than 1 yr in 1% of cases
Telangiectatic matting	Occurs in approximately 10% of patients treated; usually resolves in 3–12 mo if left untreated but in rare cases can be permanent
Pain	Lasts 1 to, at most, 7 days
Bruising	May be minimized by avoiding aspirin and ibuprofen for 10 days before and after each treatment session
Minor allergic reaction	Typically resolves within about 1 hr
Rare	
Ulceration at injection site	Can take 4 to 6 wk to heal completely; small scar may result
Anaphylaxis	Incidence is extremely low
PE or DVT	Incidence is extremely low

DVT = deep vein thrombosis; PE = pulmonary embolism.

Table 2 Sample Instructions to Patients after Sclerotherapy

NEXT APPOINTMENT _____ TIME _____

Be sure to keep your follow-up appointment so the physician can monitor your progress.

Please be considerate and give our office at least 72 hours' notice if you are unable to keep an appointment. This will allow us time to call patients who are on the waiting list for an appointment.

Please walk for a few minutes before driving home.

Wear your support hose for 48 continuous hours.

After 48 hours, remove the hose, cotton balls, and tape before getting your legs wet.

After 48 hours, wear your support hose for a minimum of 7 days during the waking hours. Note: you may continue to wear them longer if you prefer.

Do not run, do high-impact aerobics, lift weights with your legs, or do sit-ups for 2 weeks. These activities can increase the venous pressure in your legs.

For 2 weeks, do not take hot baths or showers or sit in a hot tub. The heat can cause vein dilatation. You may take a warm shower or bath after 48 hours.

Avoid aspirin and ibuprofen products for 10 days before and after each treatment. These products may increase the amount of bruising that may develop from the treatment. Acetaminophen is permitted.

For further information regarding sclerotherapy, please refer to the handout "Sclerotherapy Informed Consent and Before and After Treatment Instructions."

Preparation for Your Next Treatment

Bring your support hose.

Do not apply creams, lotions, or powders to your legs the evening before or the morning of your treatment.

Bring a pair of loose shorts to wear during your treatment.

Avoid aspirin and ibuprofen products for 10 days before and after each treatment. These products may increase the amount of bruising that may develop from the treatment. Acetaminophen is permitted.

CG, also an osmotic dehydrating agent, is not approved by the FDA and achieves sclerosis by a similar mechanism. Sodium tetradecyl sulfate (STS) and polidocanol (POL) are the most widely used detergent agents in the United States. These agents form aggregates on endothelial cell surfaces and cause endofibrosis by disrupting the integrity of the cells.

In the United States, HS has been used to treat spider and varicose veins for more than 50 years. Because it is a naturally occurring bodily substance, it does not cause allergic reactions; however, it causes patients much more pain and discomfort than either STS or POL.¹² Adding lidocaine to HS reduces the pain associated with the injections without significantly decreasing the effectiveness of treatment or increasing the incidence of complications.¹³ Even with the addition of lidocaine, injection of HS is associated with some degree of patient discomfort. Moreover, HS is more viscous than the detergent agents and thus more difficult to administer. Extravasation of HS is also associated with a higher risk of skin necrosis. CG is used primarily in Europe. It also causes localized pain at the injection sites. Kern and colleagues demonstrated in a randomized study of 150 patients comparing

CG with POL that the patients treated with CG had better clearing of the vessels.¹⁴

Of the detergent sclerosants, both STS and POL are widely used in the United States, but only STS is FDA approved. FDA approval of POL has been pending for years, and it is unclear why it has not yet been granted. POL appears to be a very good sclerosant, comparable to STS: it is safe, relatively painless, and highly effective in all vein types.^{15,16} In a 2002 randomized study comparing STS with POL, both agents were found to be safe and effective, yielding a 70% clinical improvement, and there were no significant differences in adverse effects, aside from a small decrease in ulcerations with POL.¹⁷ Nevertheless, until POL is approved by the FDA, we recommend that it not be used. Two other FDA-approved detergent sclerosants are available: sodium morrhuate (SM) and ethanolamine oleate (EO). However, both SM and EO are associated with an unacceptably high risk of complications, including but not limited to ulceration and anaphylactic reactions, and hence are rarely used. For these reasons, my practice is to use STS for sclerotherapy, and the ensuing technical discussion focuses solely on this agent.

Figure 1 A 63-year-old woman (a) before and (b) after two treatments with 0.2% sodium tetradecyl sulfate.

Figure 2 A 52-year-old woman (a) before and (b) after two treatments with 0.5% sodium tetradecyl sulfate.

Figure 3 A 36-year-old woman (a) before and (b) after four treatments with a combination of 0.5% and 0.2% sodium tetradecyl sulfate. Mild hyperpigmentation may be seen on the lateral thigh.

Sclerotherapy is an outpatient procedure performed in the physician's office. Aside from the sclerosant, few special materials are needed [see Table 3]. Because there is a risk of significant allergic reactions (albeit an extremely small risk), a fully stocked resuscitation cart including intubation equipment should be available and checked regularly to confirm that all equipment is up to date and ready for immediate use.

Technique

A variety of sclerotherapy techniques have been developed. Typically, each individual practitioner develops his or her own variation of the procedure.

STEP 1: POSITIONING AND SKIN PREPARATION

Sclerotherapy is best performed with the patient supine. On rare occasions, it may be necessary to puncture a vein with the patient standing. However, the sclerosant is not

injected until the patient has been returned to the supine position, thus allowing the vein to empty.

The skin is wiped with alcohol swabs to increase the visibility of the vessels. The sclerosant is then placed in plastic 3 mL syringes. These syringes fit more easily in the hand than tuberculin syringes and are less cumbersome to use. In addition, because injection pressure is inversely proportional to the squared radius of the plunger, a 3 mL syringe generates less pressure than a 1 mL syringe does. The endothelial cells in these small vessels are quite fragile, and using a syringe that generates less pressure substantially reduces the risk of vessel disruption.

STEP 2: CHOICE OF SCLEROSANT CONCENTRATION

The solution concentration selected depends on the size of the vessel. I use 0.2% STS for vessels less than 2 mm in diameter and 0.5% for larger vessels. The volume per injection site is generally less than 0.5 mL, but larger volumes may be preferable for reticular or small varicose veins.

At present, there is enthusiasm in the literature for the use of foam sclerotherapy, a technique in which air is repetitively injected into STS to create a foam.¹⁸ This technique is ultimately based on the work of Orbach, who in 1944 advocated expelling blood from the vein by injecting small boluses of air before injecting the sclerosant.¹⁹ The rationale for foam sclerotherapy is that the foam displaces blood in the vessel, resulting in less dilution of the solution. The sclerosant then has more contact with the surface area of the venous endothelium and thus can sclerose the endothelial cells more efficiently at lower concentrations. Of the various methods of

Table 3 Materials Needed for Sclerotherapy

Alcohol swabs	Cotton balls and tape
Protective gloves	18-gauge needles
3 mL syringes	4 × 4 in. gauze pads
30-gauge needles	Adhesive bandages

creating a foam sclerosant solution,²⁰ the method described by Tessari and colleagues appears to be the easiest.²¹ In this approach, air is injected into the solution via a three-way stopcock and two syringes. Foam sclerotherapy may be used safely in the treatment of varicose, reticular, and spider veins, with excellent results.²²

STEP 3: INJECTION OF SCLEROSANT

I use 30-gauge needles for all sclerotherapy treatments; some physicians prefer 27-gauge needles for larger reticular and small varicose veins. The needle is bent at a 45° angle, with the bevel up. Countertraction is applied with the nondominant hand, and the needle is inserted parallel to the vessel and the skin surface [see Figure 4]. As the vessel is entered, the sclerosant is gently injected. The slight reduction of pressure that occurs when the vessel is entered becomes increasingly easy to appreciate as the physician accumulates experience with sclerotherapy. Blanching of the vein is another signal of entry into the vessel. If the solution is injected outside the vein, a small superficial wheal will appear, in which case, the injection should be discontinued and a new site selected for injection. Such wheals are unlikely to be a problem with STS concentrations lower than 0.25%. When more concentrated solutions are used in larger veins, aspiration of blood ensures correct placement of the needle within the vein before injection.

STEP 4: COVERAGE AND COMPRESSION OF INJECTION AREAS

After injection, cotton balls or foam or gauze pads are secured with tape and applied to the injection areas. Compression hose (20 to 30 or 30 to 40 mm Hg) are then applied. Studies have shown that using some type of bandage or pad in addition to support hose is beneficial. The degree of compression achieved with this approach can be as much as 50% greater than that achieved with support hose alone.²³ Gauze pads or cotton balls are more cost-effective than foam pads while providing comparable compressive effects.²⁴

Compression approximates the endothelial surfaces of the vein walls after sclerotherapy, thereby reducing thrombus

formation and promoting sclerosis of the vessel. It also enhances the calf muscle pump function to help clear any solution that has progressed into the deep venous system. Reduction of thrombus formation after sclerotherapy is important for minimizing hyperpigmentation. In a multicenter randomized trial that evaluated patients who underwent bilateral sclerotherapy but who received compression to only one leg, hyperpigmentation and edema were significantly greater in the uncompressed leg.²⁵ In addition, in a recent article, Kern and colleagues found that wearing compression hose enhanced the efficacy of sclerotherapy in treating patients with telangiectasias and reticular veins.²⁶

Varying recommendations have been made as to how long compression hose should be worn after sclerotherapy. A controlled comparative trial of the effects of compression in patients with reticular and telangiectatic veins found that patients who wore hose for 3 weeks exhibited greater improvement (e.g., less hyperpigmentation) than those who did not wear hose.²⁷ However, the improvement in patients wearing hose for 3 weeks was not appreciably greater than that in patients wearing hose for 1 week. I find that it is difficult to get patients to wear compression hose for several weeks. Therefore, I have adopted the standard practice of instructing the patient first to wear the hose for 48 hours without removing them and then to wear them during waking hours only for the next 7 days.

Once the compression hose are in place, the patient is asked to walk for 15 minutes before leaving the office. This further assists in clearing any solution that may have progressed into the deep venous system.

STEP 5: SCHEDULING OF RETREATMENT

As noted (see above), multiple treatments are usually required for optimal outcome. Therefore, all patients are instructed to return in 4 to 6 weeks for assessment and possible repeat treatment. Intraluminal thrombus excision may be performed at this time. This reduces the discoloration associated with sclerotherapy. After this interval, vessels requiring further treatment are apparent, and additional injections can be performed. The average patient undergoes four to six treatments.

Complications

Although sclerotherapy is generally quite safe, complications do occur. Physicians must therefore be cognizant of the potential risks and prepared to treat any adverse events that arise. The most significant complications of sclerotherapy are allergic reactions (either minor or major), skin necrosis, hyperpigmentation, deep venous thrombosis (DVT), and telangiectatic matting. Cramping, pain, edema, and blistering from tape or compression may be observed as well. With the increased use of foam sclerotherapy for axial reflux, there have been reports of visual scotoma associated with air in the injections. These usually resolve very quickly and cause no long-term harm. There has been, however, a recent report of an air embolism causing a severe stroke secondary to a patent foramen ovale.²⁸

Minor allergic reactions are quite common. For example, localized urticaria and edema may occur secondary to histamine release. In the vast majority of cases, such reactions are

Figure 4 The standard hand position for sclerotherapy. Countertraction is applied with the nondominant hand.

self-limited, typically resolving in less than 1 hour. Itching often accompanies this response but usually resolves by the time the patient leaves the office. Should reactions persist, oral antihistamines or, on rare occasions, steroids may be required.

With the sclerosants used today, anaphylactic reactions are extraordinarily rare but can be life-threatening. The incidence of anaphylaxis with STS is not known with precision but is certainly very low. The reaction is usually mediated by immunoglobulin E and occurs within minutes of exposure. Appropriate emergency measures must be undertaken immediately, including subcutaneous administration of epinephrine, delivery of supplemental oxygen, and securing of the airway. The patient should then be given antihistamines and transferred to an emergency department for continued evaluation and treatment. As noted (see above), a properly stocked emergency response cart, including endotracheal intubation supplies and medications, is essential in any office where sclerotherapy is performed. Periodic review of procedures with staff and maintenance of the emergency medications and supplies is imperative.

Skin necrosis occurs with 0.2 to 1.2% of sclerotherapy injections.²⁹ It is a complication that produces scarring and is often unpreventable. Depending on the extent of necrosis, healing may take months. The main causes of necrosis are extravasation of the sclerosant into subcutaneous tissue, inadvertent injection into an arteriole, and vasospasm. Extravasation of the sclerosant can destroy tissue, with the degree of damage determined by the type, concentration, and amount of sclerosant used [see Figure 5]. Necrosis is rare when small amounts of dilute (< 0.25%) STS are given, but extensive skin and soft tissue necrosis has been observed when higher concentrations of STS (3%) are administered to treat varicose veins.³⁰ Inadvertent injections into the arteriole feeding the telangiectasia are impossible to prevent and probably occur frequently. In a 2001 study, pulsatile Doppler sounds could be detected above spider vein complexes in 72% of cases.²⁹ Backwash of the solution through arteriovenous shunts may cause occlusion of the arteriole and skin necrosis. Blanching of the skin often occurs with intra-arteriolar injections. Skin massage or, if spasm persists, application of nitroglycerin ointment to the skin may increase microcirculation. Why ulcerations develop in some patients but not others is unknown. The question of whether it is related to injection pressure or injectate volume also remains unanswered.

Hyperpigmentation [see Figure 6] is quite common, occurring in a significant percentage of patients, and may be caused by any of the sclerosants in current use. It is more common in persons with dark complexions and in those with dark-purple vessels. Fortunately, hyperpigmentation usually resolves with time, but the process can take months to years. Postsclerotherapy compression lowers the incidence of hyperpigmentation, and microthrombectomy of any intraluminal thrombi remaining after sclerotherapy reduces the degree of hyperpigmentation present. In a multicenter study, Scultetus and colleagues demonstrated that microthrombectomy reduces postsclerotherapy pigmentation in veins less than 1 mm in size.³¹ The latter is accomplished by puncturing the skin with an 18-gauge needle and manually expressing the thrombus. Postsclerotherapy follow-up is essential to help reduce

Figure 5 Skin necrosis on the left posterior calf of a 48-year-old woman after ultrasound-guided sclerotherapy.

hyperpigmentation. There is no firm consensus on how hyperpigmentation should be treated once it develops. Some authorities recommend the use of fade creams, whereas others advocate laser treatments to lighten the pigmentation. A 2001 study found that 80% depigmentation could be achieved with weekly subcutaneous injections of the chelating agent deferoxamine mesylate.³² That various different treatments continue to be recommended suggests that none of them are clearly superior at eliminating hyperpigmentation. The passage of time appears to be the most reliable therapy.

The precise incidence of DVT after sclerotherapy is unknown but appears to be extremely low overall. The risk is somewhat higher when more concentrated solutions are used or larger volumes administered; however, it may be minimized by performing sclerotherapy only for established indications. Treating axial reflux and larger vessels surgically, with sclerotherapy limited to an adjunctive role, will reduce the volume and concentration of solution needed. Ambulation in the physician's office after treatment will help wash away any solution that has progressed into the deep venous system.

The development of tiny new red vessels at an area of previous injection is called telangiectatic matting [see Figure 7]. Like ulceration, it is unpredictable. Excessive pressure during injections is thought to play a causative role, but the exact etiology is unknown. Telangiectatic matting is very difficult

a

to treat once it has developed. Occasionally, it resolves spontaneously, but more often, it must be addressed by means of either repeat sclerotherapy with treatment of the feeding reticular vein or laser therapy. Treatment of telangiectatic matting may, in fact, be the one potential efficacious use for laser-type devices in treating diseased leg veins.

Cost Considerations

I strongly believe that all sclerotherapy, with the exception of that performed for spontaneous hemorrhage, is cosmetic. Accordingly, in the practice to which I belong, patients seeking sclerotherapy for reasons other than hemorrhage are informed well in advance that the procedure is cosmetic and not reimbursable, and they receive a good-faith estimate of expected costs in writing. As noted (see above), venous ablation, either open or catheter directed, is the treatment of choice for symptomatic axial reflux and large varicose veins; therefore, sclerotherapy for these conditions is considered medically unnecessary.

Obtaining reimbursement from insurance carriers for sclerotherapy performed to treat small varicose veins or hemorrhage is frustrating at best. Both physicians and patients have contributed to the problem in the past by filing inappropriate claims for reimbursement of cosmetic procedures. This past misuse of insurance coverage has made it difficult to obtain reimbursement even for the one solid medical indication for sclerotherapy, hemorrhage.

Financial Disclosures: None Reported

26 MEDICAL MANAGEMENT OF VASCULAR DISEASE

Russell H. Samson, MD, FACS, RVT

Vascular surgery has evolved dramatically with the explosion of noninvasive diagnostic tools and endovascular techniques for the treatment of vascular conditions. Surgeons are now actively involved in all of these technical aspects of care, although many of us still relegate the medical management of the vascular patient to our physician colleagues. Unfortunately, we are also rarely involved in preventive measures. As a result, although we may be able to bypass or open blocked arteries and replace aneurysms with minimally invasive surgery, our patients continue to die from the other cardiovascular consequences of these diseases. The assumption that the family physician, internist, or cardiologist will take care of these issues is not necessarily correct. A number of reports have shown that atherosclerotic risk factors in patients with peripheral arterial disease (PAD) are less intensively treated than in patients with coronary artery disease.^{1,2} In a review of 195 PAD patients discharged from a tertiary care hospital in Canada, Anand and colleagues reported that fewer than half were sent home with antiplatelet medication.² Only 20% were on beta blockers, and, surprisingly, only 16% were on cholesterol-lowering medications. Clearly, this represents a failure of our responsibility to the patient.

Many factors may explain why surgeons are unwilling to be involved in the nonoperative management of their patients. These include insufficient knowledge, lack of time outside the operating room or endovascular suite, or the surgeon's fear that he or she may alienate a referring medical colleague by becoming involved in that physician's management of the atherosclerotic process. Some of the above-mentioned impediments may be valid in a given surgeon's practice, but surgeons at least should know what appropriate care is for their patients' underlying disease, if only to ensure that it is being appropriately treated. This chapter outlines the medical management of atherosclerosis and its relationship to diabetes and the dysmetabolic syndrome. Medications and lifestyle changes that can improve circulation are also described, as well as therapies to counter the negative effects of platelet activation. Treatment options for hypertension and medications for specific aspects of PAD are also discussed.

Medical Management of Atherosclerosis

Fundamental to all treatment approaches for arterial pathology is an understanding of the role of lipids in atherosclerosis. It is now well known that there is more to cholesterol than good and bad varieties and that medical treatment must be

targeted at each abnormality differently. Further, although statins are clearly the dominant medications, not all statins are equal, and other drugs may prove valuable. The beneficial effects of these drugs may go well beyond changes in lipid content. Furthermore, there are patients with asymptomatic PAD who can potentially benefit from these medications even if they have "normal" lipid levels when first screened (especially those with insulin resistance, a family history of atherosclerosis and its complications, truncal obesity, and low high-density lipoprotein [HDL] or high triglycerides). The vascular surgeon, who wishes to be more than a technician and appropriately treat PAD beyond simply intervening for extremity ischemic complications, needs to be aware of such nuances, as well as other key considerations in managing the underlying atherosclerosis process. This includes the value of exercise, good nutrition, and smoking cessation.

There are four major risk factors for the development of atherosclerosis: diabetes, smoking, hypertension, and lipid abnormalities.³ The management of diabetes and hypertension and techniques for smoking prevention are beyond the scope of this chapter but are briefly outlined.

DIABETES

The development of claudication is five times more frequent in males and three times more frequent in females who suffer from diabetes.⁴ Typically, diabetes affects the more distal infrapopliteal arteries, and given that these vessels have the poorest results with revascularization, it is not surprising that diabetics have an increased risk of amputation. Although the degree of glycemic control has never been shown to reliably predict the severity of disease, good control is clearly an important goal of therapy and should be strongly encouraged, although too aggressive control, especially in the elderly, can lead to increased complications.⁵

SMOKING

Cigarette smoking is a major risk factor for the development of PAD. Further, the greater the smoking history, the more likely will be the development and severity of atherosclerotic involvement and subsequent morbidity and mortality. Accordingly, every effort should be made to encourage the patient to quit. Numerous over-the-counter remedies such as nicotine patches have been proposed, as well as some prescription medications, such as the antidepressant bupropion HCl (Wellbutrin, Brentford, Middlesex, England) and the smoking-specific agent varenicline (Chantix, Pfizer, Mission, Kansas).⁶

However, perhaps the single most important treatment that can be offered is simply encouragement by the physician. This should be an integral part of every interaction with the patient. The excess vascular mortality of smoking decreases within 20 years to the level of the never-smoker.⁷

HYPERTENSION

Although hypertension can increase the risk of PAD two- to threefold, it is not as important a risk factor as the others listed above. However, clearly, it will be important to control, if only to prevent the associated cardiac and cerebrovascular morbidity of PAD.^{8–10} In clinical trials, antihypertensive therapy has been associated with a 35 to 40% mean reduction in stroke incidence, a 20 to 25% reduction in myocardial infarction, and a more than 50% reduction in heart failure.¹¹ It is estimated that in patients with stage 1 hypertension and additional risk factors, lowering systolic blood pressure 12 mm Hg for 10 years will prevent one death for every 11 patients treated. If cardiovascular disease or PAD is present or target end-organ damage has occurred, only nine patients would require this treatment to prevent one death.¹²

In our practice treating patients with diagnosed PAD, we have found that only 32% of patients are normotensive during their office visits or vascular laboratory evaluations.^{13,14} This may be because patients are anxious and exhibit so-called “white coat” hypertension. To overcome this limitation in pressure measurements, it has been suggested that the blood pressure be taken at the end of the visit, when the patient has had time to relax. The pressure should also be taken in a standard manner with the patient seated comfortably and with the arm resting at heart level. The medical diagnostic workup in patients with hypertension is not germane to this chapter. However, the surgeon should be aware that sudden onset of hypertension or significant exacerbation may be an indication that the patient is suffering from a correctable cause such as renal artery stenosis. If suspected because of the presence of an abdominal bruit, an aneurysm, or aortic atherosclerosis, Doppler ultrasonography will usually be the first-line test. Magnetic resonance angiography or spiral computed tomographic angiography may also obviate the need for arteriography.

Initial blood pressure control will include lifestyle and dietary changes. These should include restriction of sodium, alcohol, and unsaturated fats, as well as increasing daily exercise and intake of fruits and vegetables.¹⁵ There are now a large number of medications to choose from if drug therapy is required, and these fall into the following main groups: diuretics, alpha and beta blockers, direct vasodilators, central agents, calcium channel blockers, angiotensin-converting enzyme (ACE) inhibitors, and angiotensin II receptor blockers. Many are now generic, and different pharmaceutical companies manufacture many very similar drugs. This has led to a great deal of confusion, with multiple studies producing conflicting results. Accordingly, many physicians will follow the guidelines published by the Joint National Committee on the Detection, Evaluation and Treatment of High Blood Pressure.¹⁶ Current recommendations suggest the use of diuretics as the first line of drug therapy. Initial therapy with two drugs should be considered when the blood pressure is 20/10 mm Hg above goal. In patients with diabetes or chronic renal failure, antihypertensive

medications should be considered if the blood pressure is greater than 130/80 mm Hg, although a benefit may not be seen in patients excreting more than 1 to 2 g of protein/day. In these patients, three drugs may often be necessary.¹⁶

In patients with PAD, there has been a historical concern that the use of beta-adrenergic blockers would potentially worsen the symptoms of claudication. However, several studies have shown that this class of drugs is safe in claudicants and is an acceptable choice for lowering blood pressure.¹⁷ However, large reductions of systolic pressure and leg perfusion by any class of antihypertensive agent may result in modest worsening of claudication symptoms.¹⁸ The role of beta blockers in the prevention of perioperative events is discussed later in this chapter.

The ACE inhibitor drugs have also shown benefit beyond blood pressure lowering in high-risk groups. Specifically, in the Heart Outcomes Prevention Evaluation (HOPE) study, results from the study of 4,046 patients with PAD formed a subgroup in which there was a 22% risk reduction in patients randomized to ramipril compared with placebo.¹⁹ This was independent of lowering of blood pressure. Further, it appears from the same HOPE study that these medications may slow or prevent the onset of diabetes.²⁰ Based on this finding, the Food and Drug Administration (FDA) has now approved ramipril for its cardioprotective benefits in patients at high risk, including those with PAD. Thus, in terms of a drug class, the ACE inhibitors would certainly be recommended in these patients. However, in general, the goals of treating hypertension in patients with PAD should be similar to those of patient populations with other cardiovascular diseases.

HYPERLIPIDEMIA

The term *hyperlipidemia* has the unfortunate connotation that atherosclerosis is a result only of elevated levels of lipid, especially low-density lipoprotein (LDL). However, it is abundantly clear that other abnormalities of plasma lipids, such as triglycerides, can also be deleterious to the arterial wall.^{21,22} Further, deficiencies of some of these substances, for example, HDLs, are equally important in the development of atherosclerosis. The simplistic view that LDL is the root cause of atherosclerosis has also undergone reevaluation as research has uncovered moieties of LDL and HDL that may have differing effects on arterial pathology. It is now apparent that there are different fractions of LDL based on particle size, with the smaller particles being more atherogenic. Similarly, some fractions of HDL may be more protective. In PAD, several lipid fractions are critically important in determining the presence and progression of peripheral atherosclerosis. Independent risk factors for PAD include elevations of total cholesterol, LDL cholesterol, triglycerides, and lipoprotein(a).²³ Protective against PAD are increases in HDL cholesterol and apolipoprotein(a-1).²³ For every 10 mg/dL increase in total cholesterol concentration, the risk of PAD increases approximately 10%.²⁴ Elevations in lipoprotein(a) are also an independent risk factor for PAD, particularly in men.^{25,26}

Hyperlipidemia also implies a simplistic etiology to the manifestations of atherosclerosis, that is, that lipids enter the arterial wall and by virtue of the lipid content result in stenosis. However, the actual pathologic process is significantly more complicated, with vascular inflammation playing a critical role. Within

several days of a high-cholesterol diet, monocytes adhere to the endothelium, particularly at intercellular junctions.²⁷ The aberrations of endothelial function represent an oxidative stress to the cells and occur within minutes to hours of exposure to the noxious stimuli. Oxidative stress perturbs the cell membrane and increases endothelial permeability. Monocytes then migrate into the subendothelium, where they begin to accumulate lipid and become foam cells. These activated monocytes (macrophages) release mitogens and chemoattractants that recruit additional macrophages and vascular smooth muscle cells into the lesion. In addition, they generate reactive oxygen species that increase oxidative stress within the vessel wall and that accelerate oxidation of LDL cholesterol trapped in the subintimal space. The oxidation of LDL particles in the subintimal space promotes more foam cell formation.^{27,28} This is because the oxidized LDL is taken up via the scavenger receptor. Unlike the receptor for native LDL, intracellular levels of cholesterol do not downregulate the scavenger receptor. Accordingly, oxidized LDL continues to be taken up by the macrophage via the scavenger receptor, with the result that the macrophage becomes swollen with lipid. As foam cells accumulate in the subendothelial space, they distort the overlying endothelium and eventually may even rupture through the endothelial surface.²⁸ In these areas of endothelial ulceration, platelets adhere to the vessel wall, releasing epidermal growth factor, platelet-derived growth factor, and other mitogens and cytokines that contribute to smooth muscle migration and proliferation. These factors induce smooth muscle cells in the vessel wall to proliferate and migrate into the area of the lesion. These vascular smooth muscle cells undergo a change in phenotype from a “contractile” cell to a “secretory” cell. These secretory vascular smooth muscle cells elaborate extracellular matrix (e.g., elastin), which transforms the lesion into a fibrous plaque. In addition to elaborating extracellular matrix, the smooth muscle cells may also become engorged with lipid to form more foam cells. The lesion grows with the recruitment of more cells, the elaboration of extracellular matrix, and the accumulation of lipid until it is transformed from a fibrous plaque to a complex plaque.

The complex plaque typically is characterized by a fibrous cap that overlies a necrotic core that is composed of cell debris and cholesterol and contains a high concentration of the thrombogenic tissue factor, secreted by macrophages. In later-stage lesions, calcification may occur. Ultimately, the fibrous cap can rupture, leading to distal embolization or the accumulation of platelets on the plaque and subsequent acute arterial occlusion.

As mentioned, inflammation has been associated with the development of atherosclerosis and the risk of cardiovascular events. In particular, C-reactive protein (CRP) is independently associated with PAD,²⁹ even in patients with normal lipid levels.^{30,31} In the Physician’s Health Study, an elevated CRP was a risk factor for the development of symptomatic PAD and for peripheral revascularization.³² In patients with established PAD, an elevated CRP is an independent predictor of future cardiovascular events.³³ The measurement of CRP may also guide lipid therapy in that statin drugs lower CRP levels and the reduction in CRP levels may contribute to the benefits of statin drugs.³⁴ The JUPITER study (Justification for the Use of Statins in Primary Prevention: An Intervention Trial Evaluating Rosuvastatin) suggested that patients who exhibited elevated

levels of CRP despite so-called “normal” cholesterol levels still benefited from statin use.³⁵ This is important because as many as half of all patients with PAD may present with “normal” lipid levels. However, CRP itself is probably a marker for atherosclerosis rather than a cause. This is evidenced by a study on polymorphisms in the CRP gene, which are associated with marked increases in CRP levels and thus with a theoretically predicted increase in the risk of ischemic vascular disease.³⁶ However, these polymorphisms were not in themselves associated with an increased risk of ischemic vascular disease.

Treatment of Hyperlipidemia

Based on the knowledge that the effect of lipids on atherosclerosis is more complex than simply a detrimental effect of hypercholesterolemia, treatment programs are now directed at multiple pathways within the development of plaque. However, the dominant treatment remains reducing cholesterol. This is based on a number of large studies conducted on patients with underlying cardiovascular disease or those at risk for developing these conditions. Some of these included patients with so-called “normal” levels of cholesterol. The major studies include the Helsinki Heart Study,³⁷ the Scandinavian Simvastatin Survival Study (the “4S”),³⁸ The Cholesterol and Recurring Events (CARE) Trial,³⁹ the Program on the Surgical Control of Hyperlipidemias (POSCH),⁴⁰ the Heart Protection Study (HPS),⁴¹ and, more recently, the JUPITER study.³⁵

Diet and exercise There are several methods to alter cholesterol levels, some directed at overall levels, with others more targeted at reducing LDL or triglycerides or elevating HDL. Diet modification has always been a first-line method.⁴² Reducing cholesterol and saturated fat intake and weight loss can modestly reduce LDL and can lead to a significant reduction in triglyceride levels. Dietary fiber can assist in these beneficial results. Exercise can also result in a mild reduction in LDL and an increase in HDL.

Lipid-lowering agents Although lifestyle modification by exercise and diet has been shown to be beneficial in altering lipid metabolism, medications are often mandatory additions for the PAD patient. Unfortunately, it is also important to realize that despite the beneficial effects of a lipid-altering diet and medications, many patients are noncompliant, with discontinuance rates as high as 46% being reported.⁴³

There are now numerous alternative methods for altering lipid levels. Many of these are nonprescription “remedies,” which are, nonetheless, widely used. This chapter deals only with the dominant pharmaceutical agents, the so-called lipid-lowering drugs: statins, fibrates, niacin, ezetimibe, and bile-acid sequestrants.

Statins The statins are the most commonly used medications in the treatment of hypercholesterolemia.⁴⁴ They are also the most powerful drugs for lowering LDL cholesterol, with reductions in the range of 20 to 60%.^{45,46} Currently available statins include rosuvastatin (Crestor, Astra Zeneca, Wilmington, Delaware), atorvastatin (Lipitor, Pfizer, New York, New York), fluvastatin (Lescol, Novartis Pharmaceuticals Corp., East Hanover, New Jersey), lovastatin (Mevacor, Merck, Whitehouse Station, New Jersey), pravastatin (Pravachol, Bristol-Myers Squibb, New York, New York), and simvastatin (Zocor, Merck, Whitehouse Station, New Jersey). Fluvastatin

is somewhat less potent, decreasing LDL levels by 20 to 25% at the maximum recommended dose, whereas rosuvastatin is the most potent, reducing LDL levels by up to 52% and increasing HDL up to 14%. Statins are most effective when taken at night because this is the time when cholesterol production is maximal.

Statins are competitive inhibitors of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase, the rate-limiting step in cholesterol biosynthesis.⁴⁷ A reduction in intrahepatic cholesterol leads to an increase in LDL receptor turnover that results from an enhanced rate of hepatic LDL receptor cycling.⁴⁸ An additional benefit is a reduction in the concentration of small, dense LDL, shifting the LDL subfractions to more buoyant, less atherogenic LDL.⁴⁹ Interestingly, it is not the baseline LDL level that is the most important factor in predicting the beneficial outcome of statin use. Rather, it is the percentage reduction that seems to be critical. Most of the statins have modest HDL-raising properties (about 5%). Triglyceride concentrations fall by an average of 20% because of a decrease in very low density lipoprotein (VLDL) synthesis and to clearance of VLDL remnant particles by apolipoprotein B/E (LDL) receptors.

Although rosuvastatin would seem to be more efficacious and therefore the statin of choice, subtle differences between the statins and price considerations will impact the decision as to which statin should be used. Claims have been made that water-soluble statins such as rosuvastatin, pravastatin, and fluvastatin are less likely to cause side effects and are, as a result, better tolerated by the patient. They may also have beneficial effects on plaque stability and plasminogen activator inhibitor-1 (PAI-1) that are not seen with the lipid-soluble statins, such as atorvastatin. Also, the metabolism of pravastatin is dual (liver and kidney) and compensatory for the degree of renal insufficiency.⁵⁰ This property differs from the other agents in this class; as a result, pravastatin may be safer in patients with renal failure. However, rosuvastatin, atorvastatin, and fluvastatin do not require dose adjustment in renal failure and so may be suitable alternatives.

Side effects Adverse reactions occur less frequently with statins than with the other classes of lipid-lowering agents.

Hepatic dysfunction Although hepatic dysfunction can rarely occur, clinical consequences are exceedingly rare (0.5 to 3% occurrence of persistent elevations in aminotransferases). This primarily occurs during the first 3 months of therapy and is dose dependent. However, two randomized trials have reported no significant difference in the incidence of persistently elevated aminotransferases between statin and placebo therapy.^{38,51} The FDA labeling information includes liver function testing before and at 12 weeks following the initiation of statins, at any elevation of dose, and periodically thereafter.⁵²

Muscle injury Development of muscle toxicity remains an important concern with the use of the statins.⁵³ Myopathic syndromes associated with statins span a spectrum of complaints ranging from myalgias (2%), to myositis (0.5%), to overt rhabdomyolysis, which may be associated with acute renal failure (< 0.1%).⁵⁴ Enhanced susceptibility to statin-associated myopathy occurs in patients with chronic renal failure, obstructive liver diseases, and untreated hypothyroidism and in patients receiving concurrent therapy with a

number of drugs, particularly fibrates and those that inhibit cytochrome CYP3A4. These include cyclosporine, gemfibrozil, nicotinic acid, macrolide antibiotics (e.g., erythromycin), antifungals such as ketoconazole (Nizoral, McNeil-PPC, Fort Washington, Pennsylvania), and HIV protease inhibitors. Unlike other statins, rosuvastatin, pravastatin, and fluvastatin are not extensively metabolized by the CYP3A4 system; as a result, they have few interactions with other drugs. Despite the increased risk of myopathy associated with statin therapy, routine monitoring of serum creatine kinase (CK) levels is not recommended.⁵² Patients and clinicians should, however, remain alert for the symptoms of myopathy. In a small number of patients, coenzyme Q₁₀ may improve symptoms, but in a systematic review of the literature, there was no level I support for this treatment.⁵⁵

Although several animal studies have suggested that statin therapy is associated with an increased risk of cancer,⁵⁶ a meta-analysis of five randomized clinical trials involving 30,817 patients found no association between statin use over a 4- to 6-year period and the risk of fatal or nonfatal cancer.⁵⁷ Unusual and as yet unsubstantiated side effects include alopecia and memory disorders.

Although statins are used primarily for the treatment of hypercholesterolemia, there is growing evidence that they increase bone formation, volume, and density and reduce the risk of osteoporotic fractures, particularly in older patients.⁵⁸ There is also some evidence that statins may lower blood pressure,⁵⁹ prevent Alzheimer disease,⁶⁰ and decrease the risk of certain cancers.

Laboratory monitoring of statin therapy Once initiated, a follow-up lipid profile should be performed at 12 weeks and dose adjusted according to the desired reduction. If this cannot be achieved with the original statin, a more powerful dose or drug should be used. In general, although side effects are rare, they do appear to be dose dependent. If necessary, addition of a nonstatin lipid-lowering drug can be considered. At present, the alternative drug of choice would appear to be ezetimibe. Other agents, such as the fibrates and resins, can also be considered.

At the original follow-up, laboratory evaluation of hepatic transaminases can also be evaluated. Subsequent evaluation of hepatic function is unnecessary except if drug interactions are suspected or if transaminases are elevated by more than three times normal. Monitoring should also be considered for patients with preexisting liver disease. There is no benefit to evaluating CK levels unless the patient is symptomatic.^{61,62} Further, patients may have symptomatic myalgia but have normal CK levels. If a CK level greater than 10 times normal is encountered, the statin should be discontinued even if the patient is asymptomatic. However, it is also important to realize that CK can be elevated by other conditions, such as hypothyroidism and recent heavy exercise.

Fibrates Fibrates are effective for the treatment of hypertriglyceridemia and combined hyperlipidemia. Four fibrates are currently available in the United States: gemfibrozil, fenofibrate, clofibrate, and fenofibric acid. Clofibrate, however, is now rarely prescribed because it has been associated with cholangiocarcinoma and other gastrointestinal cancers.⁶³ Other fibrates that are available worldwide include bezafibrate and ciprofibrate.

The major effects of the fibrates are to lower serum triglycerides (by 35 to 50%) and raise HDL (by 15 to 25%). These effects are mediated at least in part by activation of peroxisome proliferator-activated receptors. This results in complex downregulation or stimulation of apolipoprotein gene expression and concomitant decreased production and increased clearance of VLDL and increased HDL-mediated reversed cholesterol transfer.⁶⁴⁻⁶⁷

The fibrates have a variable effect on serum lipoprotein(a). In one study, for example, bezafibrate reduced serum lipoprotein(a) by approximately 26% overall and by 39% in patients with values above 30 mg/dL. However, the effect of gemfibrozil on lipoprotein(a) may vary with the lipid disorder.⁶⁸ Fibrates also have a variable effect on plasma fibrinogen, with gemfibrozil having no effect and fenofibrate lowering fibrinogen. However, gemfibrozil may have a beneficial effect by reducing PAI-1.⁶⁹ An additional difference among the fibric acid derivatives is the effect on serum homocysteine. They increase with fenofibrate and bezafibrate, a potentially undesirable effect (because elevated homocysteine may be associated with the development or worsening of atherosclerosis and neointimal hyperplasia) but are unchanged with gemfibrozil.^{70,71}

Gemfibrozil Gemfibrozil, at a dose of 600 mg twice daily 30 minutes before the morning and evening meal, increases HDL cholesterol levels by an average of 11%. However, the Helsinki Heart Study showed a more prominent elevation in HDL cholesterol in the lower range of plasma HDL levels (i.e., in those at greatest cardiovascular risk).⁷² Subgroup analysis found that gemfibrozil was particularly effective in preventing heart disease in patients with high serum triglyceride concentrations (> 202 mg/dL) plus either low HDL cholesterol (< 42 mg/dL) or a high LDL to HDL cholesterol ratio (> 5.0).

Fenofibrate and fenofibric acid Fenofibrate has less risk of side effects than gemfibrozil. Dose reduction is warranted in patients with renal disease. An important drug interaction is that fenofibrate increases the clearance of cyclosporine.

Fibrates have been associated with muscle toxicity,⁷³ an effect that is more pronounced in patients also treated with a statin.⁷⁴ This effect may be mediated by competitive inhibition of CYP3A4, leading to a reduction in statin metabolism. Given that pravastatin and fluvastatin are not extensively metabolized by the CYP3A4, they may be safer when combination therapy is required with a fibrate.⁷⁵ Given that fibrates also interfere with the metabolism of warfarin,⁷⁶ the warfarin dose should be reduced by 30% in patients treated with this drug.

Niacin (Nicotinic Acid) Niacin is a well-established antilipemic agent. It comes in several formulations that include immediate-release (crystalline) and sustained-release formulations such as Niaspan (Kos Pharmaceuticals, Miami, Florida). Niacin has a variety of beneficial effects on lipid metabolism. Its major effect is to raise HDL by as much as 30 to 35%, both by reducing lipid transfer of cholesterol from HDL to VLDL and by delaying HDL clearance.^{77,78} It also inhibits the formation of VLDL and its metabolite LDL.⁷⁷ At higher doses, nicotinic acid can also lower lipoprotein(a) levels by as much as 35%.⁷⁸ Niacin may also lower fibrinogen levels.⁷⁹

Niacin is effective in patients with hypercholesterolemia and in combined hyperlipidemia associated with normal and

low levels of HDL cholesterol (hypoalphalipoproteinemia). The HDL-raising properties of nicotinic acid occur with dosages as low as 1 to 1.5 g/day.⁸⁰ In contrast, the VLDL- and LDL-lowering effects are typically seen with higher doses (3 g/day).^{77,78} In one study, nicotinic acid in a dose of 500 mg t.i.d. raised HDL cholesterol by 20% but reduced LDL cholesterol by only 5%. In comparison, a higher dose of 1.5 g t.i.d. produced more prominent changes of 33% (HDL elevation) and 23% (LDL reduction).⁷⁸

Niacin is especially helpful in combination with fibrates or statins. In a study of 269 patients, the reduction in total and LDL cholesterol with sustained-release niacin was 11% and 18%, respectively, compared with 23% and 32%, respectively, in those taking a combination of niacin and a statin.⁸¹ However, the use of nicotinic acid is often limited by symptomatic side effects. At standard doses (1.5 to 4.5 g/day), flushing occurs in 80% of cases and pruritus, paresthesias, and nausea each occur in about 20%.⁷⁸ In addition, elevations in hepatocellular enzymes are common and may lead to severe hepatotoxicity, jaundice, and fulminant hepatitis. The onset of hepatocellular injury is not predictable; therefore, regular monitoring of biochemical studies is mandatory. Crystalline niacin is preferred to most sustained-release preparations because the former is associated with a greater hyperlipidemic effect and seemingly less hepatotoxicity.⁸² However, flushing is more common with crystalline niacin. Combining niacin with a complex carbohydrate, inositol, can reduce flushing, and now many such preparations are available over the counter, usually marketed as no-flush niacin.

Therapy with nicotinic acid is initiated at 100 mg three times daily and gradually increased to the targeted dosage as tolerated.⁸⁰ Pretreatment with aspirin 30 minutes prior to dosing can minimize flushing and the other prostaglandin-mediated side effects noted below. This adverse reaction often diminishes in 7 to 10 days. Nicotinic acid is better tolerated when ingested with food, which minimizes gastrointestinal side effects. Alcohol may make the flushing more aggressive.

Some important medical consequences of niacin must be borne in mind. Most importantly, nicotinic acid causes insulin resistance. As a result, hyperglycemia may develop in susceptible patients and the glycemic state may be worsened in those already being treated for overt diabetes mellitus.⁸³ Nicotinic acid can also induce hyperuricemia and precipitate acute gouty arthritis; it should therefore be avoided in any patient with a history of gout. Hypotension can occur when used in conjunction with vasodilators, and this can aggravate angina.⁸⁴ Nicotinic acid causes a dose-dependent elevation in plasma homocysteine levels that may negate its favorable effects⁸⁵ on the lipid profile in certain subsets of patients.⁸⁶ Thus, after nicotinic acid is titrated to a stable maintenance dose, homocysteine levels should be measured.

Niaspan is a controlled-release formulation of nicotinic acid that has improved patient tolerability compared with an immediate-release preparation. In one study of 269 patients receiving a median dose of 2,000 mg/day for 48 weeks, only 4.8% discontinued the drug because of flushing.⁸⁶ However, we still find that this preparation requires a very slow increase in dosage to improve patient tolerance of the flushing. Niaspan is initiated at a dose of 500 mg nightly for 1 month, and the dosage is titrated to 1,000 mg. The standard dosage of

Niaspan is 1 to 2 g nightly. It is advised that the medication be given with a nighttime snack. The manufacturer does not recommend doses greater than 2,000 mg daily. Women may respond at lower Niaspan doses than men.

Bile acid sequestrants Bile acid sequestrants bind with bile acids in the intestines and are then eliminated in the stool. This results in interruption of the reabsorption of bile acids, which is usually 90% efficient. The ensuing reduction in the cholesterol pool lowers intrahepatic cholesterol, which promotes the synthesis of apolipoprotein B/E (LDL) receptors. The apolipoprotein B/E (LDL) receptors bind LDL from the plasma, causing a further reduction in blood cholesterol. The bile acid sequestrants also induce a minimal elevation in HDL cholesterol via intestinal formation of nascent HDL.⁸⁷

These medications are effective in patients with mild to moderate elevations of LDL cholesterol. Low doses taken before meals (8 g/day of cholestyramine or 10 g/day of colestipol or three 325 mg tablets of colesvalam b.i.d.) can reduce LDL cholesterol by 10 to 15%. A more pronounced reduction (about 24%) can be achieved at maximal recommended doses (24 and 30 g/day, respectively).^{88,89}

Bile acid sequestrants are most effective when used in combination with a statin or nicotinic acid in patients with markedly elevated plasma levels of LDL cholesterol. As an example, bile acid sequestrants and statins have synergistic actions to lower LDL cholesterol (about 50%) and raise HDL cholesterol (11 to 18%).⁹⁰

The use of a bile acid sequestrant is often limited by side effects that include constipation, bloating, nausea, and gas. They can be limited by taking large amounts of liquids. Colestipol (2.5 g) has also been given in combination with psyllium mucilloid (2.5 g), three times daily with meals; this regimen produces equivalent LDL lowering and a more favorable change in the ratio of total cholesterol to HDL cholesterol than full-dose colestipol (5 g t.i.d. with meals).⁹¹

Bile acid sequestrants may also interfere with the absorption of other medications, such as digoxin, warfarin, fat-soluble vitamins, and folic acid, so these medications should be taken at least 1 hour before or 4 to 6 hours after the sequestrant.⁹² Patients on resins may need folic acid supplementation, especially if homocysteine levels are elevated, and patients on some of these previously mentioned drugs might need dosage adjustments or close monitoring of effectiveness.

Ezetimibe This medication interferes with the absorption of cholesterol from the intestines. It can be used as a stand-alone drug (Zetia, Merck, Whitehouse Station, NJ) or in combination (Vytorin, Merck, Whitehouse Station, NJ) with the statin simvastatin.⁹²⁻⁹⁴ Like the statins, this medication can result in myopathy or hepatotoxicity, although this is less frequent. Myopathy is usually seen with drug interactions with itraconazole, ketoconazole, erythromycin, clarithromycin, telithromycin, HIV protease inhibitors, or nefazodone or large quantities of grapefruit juice (> 1 quart daily). The concomitant use of Vytorin and fibrates (especially gemfibrozil) should be avoided. The combined use of Vytorin at doses higher than 10 or 20 mg daily with amiodarone or verapamil should be avoided unless the clinical benefit is likely to outweigh the increased risk of myopathy. Because of the unknown effects of the increased exposure to ezetimibe in patients with moderate or severe hepatic impairment, ezetimibe is not recommended in these patients.

Although ezetimibe certainly reduces LDL levels, improved morbidity or mortality awaits clinical confirmation. In fact, in a recent highly controversial report, carotid intimal thickening may actually have increased with Vytorin,^{95,96} although an FDA review of that data suggests that intimal thickening was unchanged.

Antiplatelet Agents

This group of medications warrants special mention because they do not specifically affect hyperlipidemia but rather its consequences of plaque inflammation and subsequent platelet adherence and acute arterial occlusion or distal embolization.⁹⁷ In patients with PAD, a meta-analysis of all antiplatelet trials (including studies of aspirin, clopidogrel, ticlopidine, and dipyridamole) demonstrated a 23% odds reduction in ischemic events.⁹⁸

ASPIRIN

Aspirin is the most inexpensive antiplatelet drug with the most evidence supporting its use. The Antithrombotic Trialists' Collaboration meta-analysis concluded that when patients with cardiovascular disease were given aspirin, there was a consistent 25% odds reduction in subsequent cardiovascular events.⁹⁹ The study also clearly demonstrated that low-dose aspirin (75 to 160 mg) was protective and probably safer in terms of gastrointestinal bleeding than higher doses of aspirin. Unfortunately, as many as one in 20 patients may be resistant to the clinical effects of aspirin. Although this can be tested by blood or urine tests, these are seldom performed.¹⁰⁰

CLOPIDOGREL

Clopidogrel is an antiplatelet agent that has been shown to be more potent than aspirin in reducing secondary events in patients with atherosclerotic disease. In the Clopidogrel versus Aspirin in Patients at Risk of Ischemic Events (CAPRIE) trial, clopidogrel was associated with an overall reduction in primary end points, that is, stroke, myocardial infarction, or death from other vascular causes.¹⁰¹ Although the overall percentage reduction was 8.7%, the absolute change was only 0.5% (5.32% versus 5.83%). However, those with PAD had a higher rate of protection from secondary events compared with those who enrolled because of myocardial infarction or cerebrovascular disease. Patients taking clopidogrel had a higher incidence of diarrhea, rash, and pruritus than those on aspirin but had a lower incidence of other gastrointestinal disturbances and upper gastrointestinal bleeding. Further, given that the current data lack clinical trial evidence on the benefits of aspirin in patients with PAD, clopidogrel would be the preferred antiplatelet agent in this patient population.⁹⁷ However, recent data suggest that approximately 30% of patients concurrently taking proton pump inhibitors may be resistant to clopidogrel.¹⁰² The addition of aspirin to clopidogrel appears to offer no added benefit.¹⁰³

Medical Management of Specific Vascular Conditions

Although the preceding discussion covers the general principles of medical management of patients with PAD, components of this overall disease process warrant specific consideration.

CLAUDICATION

Although claudication is a manifestation of advanced PAD, it seldom leads to amputation, with the majority of patients staying stable over many years. Accordingly, treatment is usually directed at quality of life. Primarily, treatment should be aimed at lifestyle modification and most importantly at the implementation of a routine walking exercise program to allow improvement in walking distance. Unfortunately, compliance is poor with these methods of management usually because the patient is limited by pain or because of cardiac or respiratory conditions.

Treatment of claudication with medicines may improve both pain-free walking distance (PFWD) and maximal walking distance (MWD), but this should be viewed as supplementary. Currently, FDA approval for the treatment of intermittent claudication is limited to pentoxifylline and cilostazol, with the latter appearing to be more effective in increasing PFWD and MWD. Although many patients will demonstrate an improvement, only half will report subjective improvement in their quality of life following treatment with cilostazol. Further, many patients may simply exhibit a placebo effect.

A number of other medications that are used in Europe, Latin America, and Asia have shown promising results, but further clinical evaluation is necessary. New treatment regimens are under evaluation, and they should be accepted only after they have been proven beneficial and appropriately conducted as scientifically based clinical trials.

Pentoxifylline

Pentoxifylline is a methylxanthine derivative that is now widely available as a generic pharmaceutical. Its primary effect is thought to be an improvement in red blood cell deformability. Other effects include a decrease in blood viscosity, platelet aggregation inhibition, and a reduction in fibrinogen levels.

Although there have been numerous reports of good results concerning pentoxifylline's effects in the treatment of intermittent claudication, two major randomized, double-blind studies have provided conflicting results.^{104,105} The first of these two trials compared pentoxifylline with placebo over a 24-week period.¹⁰⁴ The pentoxifylline-treated group had an improvement in PFWD (45% versus a 23% improvement in those given placebo [$p = .02$]) and MWD (32% improvement versus 20% of those treated with placebo [$p = .04$]). In common with other claudication studies is the fact that placebo improved PFWD by 23%. Further, despite significant improvements in PFWD and MWD, subjective assessment was not improved in the pentoxifylline group. The second study randomized 150 patients to 1,200 mg a day of pentoxifylline ($n = 76$) or placebo ($n = 74$).¹⁰⁵ Differing from the findings of the previous study, these investigators found no improvement in PFWD and only a trend that suggested an improvement in MWD in patients given pentoxifylline ($p = .09$). However, certain subpopulations of patients showed significant improvement in both PFWD and MWD when compared with placebo. Patients with moderate versus mild disease tended toward significant improvement, and those with chronic duration of the disease (greater than 1 year) also tended toward significance. Unfortunately, the beneficial effects of pentoxifylline may wear off with long-term administration. In a study by Ernst and colleagues, MWD at certain

time intervals during the study period did demonstrate significant improvement; however, no significant benefit in PFWD or MWD was observed after 12 weeks of pentoxifylline therapy.¹⁰⁶

It appears, then, that pentoxifylline may offer a modest improvement in walking distance in some patients, but this may be too small to offer any improvement in quality of life. However, given that this medication is relatively free of side effects and inexpensive, it is frequently used as a first-line medication. The dosage may need to be adjusted if used with other methylxanthine derivatives (e.g., aminophylline or theophylline).

Cilostazol

Cilostazol is a phosphodiesterase type III inhibitor prescribed at a dose of 100 mg twice a day and is now the most widely prescribed medication for improvement in walking distance. It is also available in a generic form and is thought to exert its mechanism of action by inhibiting cyclic adenosine monophosphate (cAMP) phosphodiesterase. By increasing the levels of cAMP in platelets and blood vessels, there is a resultant inhibition of platelet aggregation and a promotion of smooth muscle cell relaxation. Other additional pharmacologic properties include a modest positive lipid effect, mildly increasing HDL cholesterol, and decreasing triglycerides.¹⁰⁷ In vitro studies have shown that there may be a reduction in smooth muscle cell proliferation.¹⁰⁸ As with pentoxifylline, it does not reduce or prevent worsening plaque burden.

Multiple studies have compared cilostazol with placebo with an average improvement in MWD of 140 meters, with 51% of study participants perceiving this improvement versus 30% for those on placebo. Given that this distance may or may not improve quality of life, it is important for the prescribing physician to inform the patient that pain-free walking will be unlikely, and although improved MWD may occur, this may still not be satisfactory.

Given that cilostazol is associated with nausea, diarrhea, palpitations, and headache, it is important that a trial dose of the medicine be prescribed prior to initiating long-term therapy because many patients will not be able to tolerate the medication. In some patients, starting with half the dose and gradually increasing the dose can allow them to take the medication. Cilostazol is contraindicated in patients with congestive heart failure of any severity because other phosphodiesterase inhibitors, but not cilostazol specifically, have been shown to decrease survival rate compared with placebo in patients with class 3 to class 4 (New York Heart Association) congestive heart failure.¹⁰⁹ Further, cilostazol is partially metabolized in the liver by the CYP3A4 or the CYP2C19 enzymes. Because of this, other drugs that rely on these specific hepatic enzymes may increase cilostazol levels. Examples include antifungals, erythromycin, some selective serotonin reuptake inhibitors, and omeprazole. Although the concurrent use of these medications is not discouraged, one may want to consider reducing the daily dose of cilostazol to 50 mg twice a day.

Statins

As mentioned already, all patients with PAD should be considered for a statin irrespective of their underlying cholesterol levels because of the protective effect of statins on

cardiovascular morbidity and mortality. However, statins have also been shown to improve walking distance. Mohler and colleagues performed a randomized, double-blind, parallel-design study that included 354 persons with claudication attributable to PAD.¹¹⁰ Patients were treated with placebo, atorvastatin 10 mg per day, or atorvastatin 80 mg per day for 12 months. The outcome measures included a change in treadmill exercise time and patient-reported measures of physical activity and quality of life based on questionnaires. Maximal walking time after 12 months of treatment with atorvastatin did not change significantly. However, there was improvement in pain-free walking time after 12 months of treatment for the 80 mg ($p = .025$) group compared with the placebo group. A physical activity questionnaire demonstrated improvement in ambulatory ability for the 10 and 80 mg groups ($p = .011$), whereas two quality of life instruments, the Walking Impairment Questionnaire and Short Form 36 Questionnaire, did not show significant change.

Mondillo and colleagues studied 86 patients with PAD, intermittent claudication, and total cholesterol levels greater than 220 mg/dL.¹¹¹ Patients were enrolled in a randomized, placebo-controlled, double-blind study. Forty-three patients were assigned to simvastatin (40 mg/day); the remaining 43 patients were assigned to placebo treatment. All patients underwent an exercise test and clinical examination and completed a self-assessment questionnaire at 0, 3, and 6 months. Pain-free and total walking distance, resting and postexercise ankle-brachial indexes, and questionnaire scores were determined at each follow-up. At 6 months, the mean PFWD had increased 90 meters (95% confidence interval [CI] 64 to 116 meters; $p < .005$) more in the simvastatin group than in the placebo group. Similar results were seen for the total walking distance (mean between-group difference in the change, 126 meters; 95% CI 101 to 151 meters; $p < .001$). There was also a greater improvement in claudication symptoms among patients treated with simvastatin. The effects on walking performance and questionnaire scores were also significant at 3 months.

McDermott and colleagues attempted to evaluate whether such improvement was related to achieved cholesterol levels in patients with and without PAD.¹¹² They found that statin use was associated with superior leg functioning compared with no statin use, independent of cholesterol levels and other potential confounders, such as aspirin, ACE inhibitors, vasodilators, or beta blockers. Their data suggest that the non-cholesterol-lowering properties of statins may favorably influence functioning in persons with and without PAD.

Aspirin

Aspirin has not been demonstrated to improve walking distance or symptoms in patients with intermittent claudication. Further, specific studies in the PAD population using aspirin have not shown a statistically significant reduction in cardiovascular events.⁹⁹ Thus, although antiplatelet drugs are clearly indicated in the overall management of PAD, aspirin does not have specific FDA approval for use in this patient population.¹¹³

Clopidogrel

There is no evidence to suggest that the symptoms of claudication are reduced by long-term treatment with clopidogrel.

STROKE

There is clear evidence that medical management can significantly reduce the occurrence of stroke. Accordingly, it would seem almost mandatory that patients with carotid artery plaque should be treated with a statin and an antiplatelet agent such as aspirin, aspirin and dipyridamole combination, or clopidogrel, although which medication is superior is still a matter of conjecture.^{114,115} Current data would suggest that combination therapy of aspirin and dipyridamole may be superior to aspirin alone,¹¹⁴ but there are no compelling data to suggest that this combination is superior to clopidogrel. Also, warfarin adds no advantage to aspirin in the prevention of recurrent ischemic stroke.¹¹⁶

In the HOPE study, the addition of the ACE inhibitor ramipril added stroke protection irrespective of its effects on blood pressure.¹⁹ However, hypertension should be actively and aggressively controlled,¹¹⁷ except in the very elderly, for whom more moderate control may be safer.

Also, the use of statins perioperatively may reduce the incidence of perioperative stroke.¹¹⁸ In a nonrandomized retrospective analysis, Kennedy and colleagues found a protective effect of statin therapy in symptomatic patients pretreated at the time of carotid endarterectomy (CEA).¹¹⁸ This was not seen in asymptomatic patients. The latter finding may be because the plaque of asymptomatic patients is not in a state of inflammation that would be ameliorated by statins. This hypothesis is supported by histologic studies performed by Molloy and colleagues.¹¹⁹ They performed an observational study on 137 patients undergoing CEA. Patients on statins were less likely to have had symptoms in the 4 weeks before CEA ($p = .0049$) and were less likely to have spontaneous cerebral embolization detected by transcranial Doppler ultrasonography ($p = .0459$).

Beneficial results following CEA were also demonstrated by McGirt and colleagues.¹²⁰ Adjusting for all demographics and comorbidities in multivariate analysis, statin use independently reduced the odds of stroke threefold (odds ratio [OR] [95% CI], 0.35 [0.15 to 0.85]; $p < .05$) and death fivefold (OR [95% CI], 0.20 [0.04 to 0.99]; $p < .05$).

There are also data that show that initiating statins after an ischemic stroke can improve recovery.^{121–123} Statin use prior to ischemic stroke is also associated with reduced mortality and better recovery.¹²⁴ Unfortunately, despite these benefits, statin use remains low (40%) following CEA.¹²⁵ The relationship between serum lipid levels and recurrent carotid stenosis has been postulated for many years^{126–128} and reconfirmed in recent literature by LaMuraglia and colleagues.¹²⁹ These same authors also showed that concurrent administration of a lipid-lowering drug had a profound effect on early recurrent carotid stenosis and that these drugs might have other relevant properties that might promote the anatomic durability of the CEA reconstruction. Such effects may include the decrease in the inflammatory response in the vessel wall, the increase in circulating endothelial progenitor cells, and the promotion of smooth muscle cell apoptosis, all of which have been described with the use of statins and are known to have a role in the restenotic process.^{130,131}

Although perioperative clopidogrel may also help reduce postendarterectomy neurologic events, increased bleeding has prompted us to discontinue this medication a week prior to endarterectomy except in patients who are having ongoing

symptoms. However, antiplatelet agents such as clopidogrel should be started at least 3 days prior to carotid stenting and continued for at least 3 months thereafter.

Perioperative Medications

Based on evidence that statins may have benefit in reducing early ischemic events following acute coronary syndromes and coronary revascularization,¹³² investigators began to evaluate whether similar reductions in cardiac morbidity could be achieved with statins in the vascular patient.^{133,134} However, unless LDL levels are driven very low, regression of atherosclerosis occurs only in a minority of patients, if at all, yet clinical benefits of statins are seen often within 6 months of initiating therapy. This suggests that factors other than cholesterol lowering or plaque regression are also important in improving outcome.

The Statins for Risk Reduction in Surgery (StaRRS) study is a retrospective study that recorded patient characteristics, past medical history, and admission medications on all patients undergoing CEA, aortic surgery, or lower extremity revascularization over a 2-year period (January 1999 to December 2000) at a tertiary referral center.¹³⁵ Complications occurred in 157 of 1,163 eligible hospitalizations and were significantly fewer in patients receiving statins (9.9%) than in those not receiving statins (16.5%, $p = .001$). The difference was mostly accounted for by reductions in myocardial ischemia and congestive heart failure. After adjusting for other significant predictors of perioperative complications (age, gender, type of surgery, emergent surgery, left ventricular dysfunction, and diabetes mellitus), statins still conferred a highly significant protective effect (OR 0.52, $p = .001$).

Kertai and colleagues studied 570 patients (mean age 69 $\pm$ 9 years, 486 males) who underwent abdominal aortic aneurysm (AAA) surgery between 1991 and 2001.¹³⁶ The main outcome was a composite of perioperative mortality and myocardial infarction within 30 days of surgery. Perioperative mortality or myocardial infarction occurred in 51 (8.9%) patients. The incidence of the composite end point was significantly lower in statin users compared with nonusers (3.7% versus 11.0%; crude OR 0.31, 95% CI 0.13 to 0.74; $p = .01$). Beta blocker use was also associated with a significant reduction in the composite end point (OR 0.24, 95% CI 0.11 to 0.54). Patients using a combination of statins and beta blockers appeared to be at lower risk for the composite end point across multiple cardiac risk strata; in particular, patients with three or more risk factors experienced significantly lower perioperative events.

Durazzo and colleagues randomly assigned 50 patients to receive atorvastatin and 50 patients to placebo once a day for 45 days, irrespective of their serum cholesterol concentration.¹³⁷ Vascular surgery was performed on average 30 days after randomization, and patients were prospectively followed up over 6 months. The incidence of cardiac events was more than three times higher with placebo (26.0%) compared with atorvastatin (8.0%; $p = .031$).

Clearly, the effect of statins on outcome noted in these studies showed that a beneficial effect occurred more rapidly than can be explained by a simple reduction in low-density cholesterol levels. This appears to support the concept that statins have an antiinflammatory effect on coronary vasculature, thus

reducing sudden coronary thrombosis.^{138,139} It should be noted, however, that not all evaluations prove a beneficial effect of statins on cardiovascular surgery outcomes.¹⁴⁰

Although commonly used for their cardioprotective effect, perioperative beta blocker use has recently been questioned because of an apparent slight increase in stroke. However, this has not been our experience, and we continue to prescribe these medications prior to and during major intra-abdominal arterial surgery. Antiplatelet agents are routinely avoided for at least a week to 10 days before such procedures, especially if spinal or epidural anesthesia is anticipated.

GRAFT PATENCY

Two articles suggest that statin therapy may also play a role in graft patency,^{141,142} and we are currently evaluating the data in the PREVENT III study to see if these data can be confirmed in this large study of infrainguinal vein bypasses.¹⁴³

Henke and colleagues evaluated 293 patients who underwent 338 infrainguinal bypass procedures with autologous veins ($n = 218$), prosthetic grafts ($n = 88$), or composite prosthetic vein grafts ($n = 32$).¹⁴¹ Statin drugs were taken by 56% of patients, ACE inhibitors by 54% of patients, and antiplatelet agents or warfarin sodium by 93% of patients. Statins were associated with increased graft patency (OR 3.7; 95% CI 2.1 to 6.4) and a lower rate of amputation. Abbruzzese and colleagues performed a retrospective analysis of consecutive 172 patients who underwent 189 primary autogenous infrainguinal reconstructions with a single segment of great saphenous vein.¹⁴² Patients were categorized according to concurrent use of a statin (94 in the statin group, 95 in the control group). Although there was no difference in primary patency, patients on statins had higher primary-revised (94% $\pm$ 2% versus 83% $\pm$ 5%; $p < .02$) and secondary (97% $\pm$ 2% versus 87% $\pm$ 4%; $p < .02$) graft patency rates at 2 years. The risk of graft failure was 3.2-fold higher for the control group. Perioperative cholesterol levels (available in 47% of patients) were not statistically different between groups.

AORTIC ANEURYSMS

Given that AAA formation may be a result of inflammation and extracellular matrix remodeling mediated by matrix metalloproteinases (MMPs) and that statins have an antiinflammatory effect, it is not surprising that a possible beneficial effect of statins on decreasing aneurysm development has been investigated. Kalyanasundaram and colleagues studied this in rats and found that AAAs in rats given statins were smaller than in those fed a placebo.¹⁴⁴ MMP-9 and nuclear factor- κ B protein levels were also decreased in the aortas of simvastatin-treated animals. Similar findings were also noted by Steinmetz and colleagues, who found that the mechanisms of this effect were independent of lipid lowering and included preservation of medial elastin and smooth muscle cells, as well as altered aortic wall expression of MMPs and their inhibitors.¹⁴⁵ Nagashima and colleagues evaluated the aortic wall in patients, some of whom had been on cerivastatin.¹⁴⁶ Cerivastatin significantly reduced the tissue levels of both total and active MMP-9 in a concentration-dependent manner ($p < .001$) by inhibiting the activation of neutrophils and macrophages. However, cerivastatin has been withdrawn from the US market.

There are also experimental suggestions that doxycycline, a generic tetracycline, may reduce aneurysm growth.^{147,148} Given that the side effects of this drug are very rare, except for increased photosensitivity, I routinely use 100 mg daily in the management of small AAAs.

NONATHEROSCLEROTIC VASCULAR DISEASE

The vascular specialist may be confronted with patients suffering from a multitude of nonatherosclerotic conditions affecting the arterial system. These usually will manifest with Raynaud syndrome and, in advanced cases, with digit ischemia and gangrene. In such patients, an attempt should be made to differentiate the underlying etiology and to alleviate the symptoms. In most patients, avoidance of cold and digit injury is all that is required. However, in advanced cases in which ulceration or gangrene is evidenced, medications may be helpful. These will include vasodilators such as calcium channel blockers. Antiplatelet agents as well as pentoxifylline and clopidogrel have been used, but there is no level I evidence supporting their use.

Miscellaneous Medications: Over-the-Counter Medications, Vitamins, and Herbs

Atherosclerosis is a multifactorial process related to interaction between a multitude of genetic processes and environmental pressures. Not surprisingly, many medications, herbs, and vitamins have been suggested to have beneficial effects.¹⁴⁹ For example, homocysteine-lowering vitamin B₁₂ compounds and folic acid have been touted as effective. However, although elevated levels of homocysteine are associated with premature development of atherosclerosis and coronary neointimal hyperplasia following stents, lowering homo-

cysteine has not been proven to effect clinical outcome.^{85,150} Similarly, antioxidants such as vitamin E have also not been effective.¹⁵¹ Despite a large amount of literature, very few articles have enough scientific merit to warrant serious consideration, and many offer conflicting results. This accounts for the confusion and suspicion that surround many of these treatments.

Currently, none of the treatment modalities except diet and fish oils¹⁵² can be strongly suggested as beneficial for most patients. However, individual patients may benefit from some of these miscellaneous compounds. Examples would be patients on dialysis or those who are nutritionally deficient, such as the very elderly.

Summary

The ravages of atherosclerosis and other rarer conditions affecting the vascular system continue to account for most deaths in the developed world. Increasingly, vascular surgeons are finding themselves at the forefront of the fight against this scourge. Although advances in the technical method of treatment, such as angioplasty, stents, endografts, atherectomy, and lytic therapy, are all achieving some success in reducing morbidity and mortality, it is anticipated that optimal medical management will have an even more pronounced salutary effect. As such, the modern vascular surgeon must be able not only to operate and dilate but also to medicate.

Financial Disclosures: None Reported.

27 LOWER-EXTREMITY ULCERS

Robert D. Galiano, M.D.

A lower-extremity ulcer presents a unique window into a patient's health. The term ulcer implies a nonhealing wound, meaning that an ulcer is most likely to be present in a patient with an underlying pathophysiologic derangement. Accordingly, the surgeon treating a leg wound is obliged to address any impediments to healing that exist, whether local or systemic, with a well-designed therapeutic plan. Although there are literally scores of different types of lower-extremity ulcer [see Table 1], it is neither practical nor necessary for the surgeon to learn a specific treatment for every single type. In most cases, it is better to develop a logical framework that emphasizes the common features shared by most leg ulcers (rather than the differences). Such a focus on the shared causal factors of lower-extremity ulcers, coupled with a knowledge of modern wound care and an appreciation of the unique anatomy of the leg and foot, will facilitate patient understanding, enhance communication between consultants and primary care physicians, and, most important, enable efficacious patient care.

The following characteristics are common to most lower-extremity ulcers.^{1,2}

1. Ischemia. Several factors, including peripheral arterial disease and edema, contribute to the prevalence of tissue ischemia in the lower extremity. Ischemia may be local or regional, or it may be dependent, associated with episodic ischemia-reperfusion injury. Cells require oxygen to carry out basic metabolic functions, fight infections, and heal wounds.³⁻⁵ Edema contributes to tissue hypoxia by increasing the distance between a cell and the nearest capillary.⁶
2. Age. Most leg ulcers occur in elderly persons. Many comorbid conditions (e.g., diabetes, venous stasis, and peripheral arterial disease) are age dependent, and aged cells lose much of their ability to respond to sublethal ischemia.⁷⁻⁹ Consequently, a given degree of ischemia typically has a greater impact on an elderly person than on a young one.
3. The presence of bacteria. Most chronic ulcers are colonized by bacteria in the form of a biofilm, which is difficult to treat and perpetuates the inflammatory response within a wound.¹⁰ Although the adverse effects of bacteria on wound healing have long been noted, those of biofilm, which does not always give rise to an overt phenotype or infectious picture, have been underappreciated. Indeed, a stalled, nonhealing wound is one of the more common presentations of biofilm. Many of the current advances in wound care practice and dressing use focus on management of the bioburden borne by the wound.

Acknowledging and addressing each of these common factors will allow the surgeon to heal the vast majority of leg ulcers, either surgically or nonsurgically; ignorance of these factors will result in a haphazard approach to leg ulcer care that will inevitably be associated with inferior outcomes.

Wound care practitioners may come from any of several medical specialties. In my view, however, lower-extremity ulcers are best treated when the expertise and know-how of an interested surgeon are closely integrated into patient care. Given that the majority of problem leg wounds occur in patients with significant comorbid

conditions, the involvement of a lower-extremity surgeon is crucial for ensuring that a patient is offered a comprehensive set of management options. One potential obstacle to such involvement, however, is that most surgeons complete their surgical residencies and fellowships without a thorough grounding in wound care. Many, in fact, are still unaware of any dressings other than wet-to-dry dressings. Today, routine management of leg wounds is often left to nurses, physical therapists, and other nonsurgical specialists. Although these practitioners are certainly capable of treating patients with uncomplicated lower-extremity ulcers, it is important to recall that an understanding of how the body heals in response to injury lies at the heart of all surgical care. It is time that surgeons reengaged themselves in the management of wounds, particularly lower-extremity wounds: surgery is the discipline that is best suited, by both training and inclination, to assume the care of these complex, challenging, and often frustrating problems. There is much room for improvement in this rapidly evolving field, and the intellectual and professional rewards to be gained from increased integration of surgeons into the care of patients with leg wounds are enormous.

The goal of modern leg wound care should be expeditious closure and long-term durable coverage, followed by carefully tailored preventive measures. Unfortunately, prevention is relatively neglected in this discipline. For example, a patient with a diabetic foot ulcer may require an Achilles tendon-lengthening procedure to deal with the ankle equinus and the resulting tendinous derangements that shift the weightbearing pressures to the area under the metatarsal heads. A program of offloading and local wound care may heal the ulcer, but recurrence is predictable, often even with the best orthotics, unless the stiff, foreshortened tendon is lengthened and gait biomechanics are restored. The high risk of recurrence—and the easiness of the operation that prevents it—will not be appreciated by a clinician who is not familiar with lower-extremity surgery. Many wounds can be healed by means of offloading and dressing changes, but it is probable that in the future, best-practice management of these lesions will include interventions aimed at minimizing ulcer recidivism, often by addressing any anatomic derangements that may have given rise to the ulcer in the first place.

Before surgical measures or advanced dressings are even considered, much can be done to enhance the healing potential of a lower-extremity ulcer.^{2,11-13} The main goal of any intervention should be to ensure that oxygen and nutrients are reaching the cells within the wound. For most wounds, the most important steps toward this goal are offloading and control of edema. With good wound care, appropriate antibiotic therapy (when indicated), and complete bed rest, even a large ulcer may heal without further treatment. Indeed, it is the dependent position of the lower extremity and the absolute requirement of most patients to ambulate that indirectly accounts for failed ulcer healing in many cases. If the dependent position can be changed and the patient can elevate the leg, the edema will be diminished and local tissue perfusion will be improved. Another step that is often neglected is ensuring adequate hydration, particularly in patients who are hospitalized or

have recently undergone surgery. Hydration enhances preload and ensures that arteriovenous shunting does not occur to divert blood away from the cutaneous tissues. Control of pain is also important to minimize sympathetic-induced vasoconstriction. Smoking cessation is beneficial: smoking impairs vascular flow, reduces vasodilatation, and accelerates the formation of atherosclerotic disease in vessels. Counseling should therefore be offered to all patients who use tobacco. The extremity should be kept warm so as to open up capillary beds and enhance tissue perfusion. Supplemental oxygen may be helpful for patients with a regional or systemic malperfusion state.

Chronic Wounds and Problem Wounds

As discussed elsewhere [see 1:7 *Acute Wound Care*], wounds normally progress through several temporally overlapping phases of healing. A chronic wound, however, does not progress through all of these phases but is arrested in one of them, usually the inflammatory phase. For practical purposes, a chronic wound can be defined—and, until comparatively recently, generally has been defined—in strictly temporal terms, as a wound that has not healed after 3 months. This once-standard definition is now being reconsidered, on the grounds that it may subject patients to need-

lessly prolonged courses of therapy, it may be used to deny advanced treatments to patients, and it fails to take into account the dynamic nature of wound healing, whereby wounds may improve, stall, and then improve again.

A better definition of a chronic wound is one that has fallen off the trajectory of expected healing.¹⁴ This newer definition has implications for clinical practice, in that it emphasizes the importance of measuring the wound periodically. The wound should be measurably smaller during each office visit: typically, an actively healing wound should show a reduction in area or volume of approximately 10% per week.¹⁵ If the wound is healing at a lesser rate or is scarcely healing at all, an immediate effort should be made to investigate the reason for the delay. There is no time for complacency (e.g., “Let’s see how it’s doing next month”), because the stalled wound is symptomatic of a significant underlying problem. It is imperative for the surgeon to consider possible causes—for example, infection or bacterial colonization. Often, an office debridement is necessary at this stage to reduce the accumulation of tenacious biofilm. If the wound shows no evidence of healing despite vigilant wound care, a biopsy should be considered, particularly if the wound has been present for more than 3 months. Other potential diagnoses besides malignancy should be considered as well, including vasculitis, pyoderma gangrenosum, and fungal or mycobacterial infection.

A number of clinical trials have shown that the rate of healing in the first 30 days after the initiation of good wound care is strongly predictive of an ulcer’s ultimate fate, especially in the case of diabetic and venous stasis ulcers: the lesions that eventually heal are the ones that show the highest initial healing rates.¹⁶⁻²⁰ This observation, though perhaps intuitively obvious, is not always appreciated, nor are its lessons always correctly applied. Part of the problem is that many ulcers are not evaluated frequently enough in the outpatient setting. Weekly measurement is essential for evaluation of healing potential. In fact, it is likely that in the future, the benchmark measured by patients, peers, and insurance companies to evaluate a wound care practitioner’s success will be time to ulcer healing. If an ulcer eventually heals after 9 months, this is still a success in some ways, but one may reasonably wonder whether the time away from work, the cost of dressings, and the multiple office visits might have been substantially reduced if the wound care practitioner had more frequently evaluated the rate of healing, had aggressively and preemptively rethought his or her approach, and perhaps had resorted to different therapeutic measures.

Instead of thinking in terms of acute wounds versus chronic wounds, as has been traditional, it may be more useful to think in terms of uncomplicated wounds versus problem wounds.² The

Table 2 Conditions That Interfere with Healing

- Immunosuppressive medications

- Recent major surgery
- Smoking
- Malnutrition (particularly acute malnourishment or a recent catabolic state)
- Infection
- Age
- Diminished tissue perfusion
- Radiation

category of problem wounds encompasses not only chronic wounds but also wounds occurring in persons whose comorbid conditions will almost certainly result in a protracted course of healing. Such persons include most elderly and hospitalized patients, but there are numerous other conditions besides advanced age and hospitalization that can impair healing [see Table 2]. For example, a week-old Wagner stage 2 ulcer in a diabetic patient is a problem wound and should be treated promptly and comprehensively with offloading, moist wound care, and frequent inspections. A dehiscence at a saphenous vein harvest site in a patient who underwent a cardiac bypass is also a problem wound, both because of the swelling typically present and because of the likelihood of bacterial colonization in the relatively hypovascular subcutaneous tissue of the thigh. The mode of injury also plays a role in determining whether a wound is a problem wound; for example, a heavily devitalized wound in an 18-year-old patient will heal as poorly as a chronic wound if it is not adequately debrided and wound perfusion is not ensured. By preemptively addressing potential impediments to healing, the surgeon can minimize complications, shorten the time to healing, and help the patient return to work in an expeditious fashion.

Incidence and Epidemiology

It is estimated that at any point, the incidence of lower-extremity ulcers in the United States may be as high as 1%.²¹ The actual number of afflicted patients will rise as a consequence of the extension of the expected average lifespan, the proportional increase in atherosclerotic vascular disease, and the growing epidemic of obesity and associated diabetes mellitus.

The transition of baby boomers from middle age to the ranks of the elderly (over the age of 65) is already occurring, and it is estimated that by 2030, the elderly will constitute 20% of the U.S. population.²² Persons older than 85 years constitute the most rapidly growing segment of the population. As noted (see above), by far the greatest number of ulcers occur in the elderly, both because of the increased incidence of atherosclerosis and because of the parallel increase in venous stasis disease.

In parallel with the increase in the elderly population, there is also a substantial increase in the diabetic population. The United States is witnessing (and leading) the dual global epidemics of diabetes and obesity. There are nearly 21 million people with diabetes in the United States, 6 million of whom are unaware that they have the disease.²³ Approximately 15% of these 21 million are at significant risk for the development of a foot ulcer. Indeed, 60% of lower-extremity amputations unrelated to trauma are performed in diabetic patients.²³ Most of these amputations are preventable. The continuing increases in the incidence of atherosclerotic disease, diabetes, and venous stasis disease make it essential for surgeons to improve their awareness of and competence in the management of wounds in the lower extremity.

Anatomic Considerations

Several unique anatomic and functional factors predispose the lower extremity to ulceration. These factors include the relentless effects of gravity and the repetitive trauma of ambulation. Another factor is the formidable challenges involved in transporting blood from the heart to the foot and back. The vascular tree of the foot is a terminal capillary bed, like that in many other organs, but it is exposed to an enormous pressure gradient that is not present in other parts of the body. In humans, the lower extremities evolved differently from the upper extremities (to enable a bipedal gait),

and the limitations and compromises attendant on this evolution are evident in the predisposition of the legs and feet to ulcerate.

The characteristics of the skin of the lower extremity play a role in ulceration. The skin in this area is taut, with minimal intrinsic laxity, and this tautness has implications for flap design.²⁴ Foot skin is extremely thick, and calluses form readily in response to pressure. Unfortunately, excess callus formation can exacerbate pressure in the sole of a diabetic person's foot. Obesity and lymphedema can alter the barrier function of the skin, as well as diminish cellular perfusion²⁵; lymphedema is particularly damaging, in that the accumulation of fluid in the interstitial space causes a relative hypoxia coupled to altered macrophage function in conjunction with the induction of a chronic inflammatory state and tissue fibrosis.²⁶ Contact sensitivities are common and may influence compliance with the wearing of dressings and compression garments. Lipodermatosclerosis may develop as the result of chronic extravasation of red blood cells into the skin and deposition of hemosiderin within macrophages. Either hypo- or hyperpigmentation may occur, along with the characteristic "woody" firmness of subcutaneous fibrosis.²⁷⁻²⁹ Venous eczema is common in patients with venous ulcers; it is probably an inflammatory process and can generally be distinguished from cellulitis on the basis of its chronicity, its poorly demarcated borders, and its pruritic, scaly nature.

The tendons also play a significant role in the etiology of diabetic forefoot ulcers, and their functional relations must be addressed when an amputation is to be performed. Dysregulation of the tendons is a frequent finding in limb ulcer patients. Chronic hyperglycemia leads to glycosylation of collagen, with subsequent loss of elasticity in connective tissues, including muscle, tendons, and skin; an example is glycosylation of the Achilles tendon, which destroys its flexibility and prevents adequate dorsiflexion during normal gait. The forefoot then bears the brunt of the person's weight during walking, and the accumulated stress, particularly in the setting of underlying neuropathy, culminates in a stereotypical diabetic forefoot ulcer (the so-called *mal perforans* ulcer). Correction of underlying biomechanical abnormalities and treatment of underlying medical conditions are as important to the overall treatment plan as debridement and wound care are.

The cutaneous innervation of the leg skin must also be taken into account. The nerves to the lower extremity include the common peroneal nerve, the superficial peroneal nerve, the deep peroneal nerve, the sural nerve, the saphenous nerve, and the tibial nerve. The branches in the foot are the medial plantar nerve, the lateral plantar nerve, and the calcaneal branch. The foot is predisposed to neuropathy for unknown reasons, one of which is almost certainly local-regional ischemia. This predisposition is particularly relevant to the pathogenesis of diabetic neuropathic foot ulcers; chronic tissue hyperglycosylation and fibrosis probably play roles as well. The medial and lateral plantar nerves travel through the tarsal tunnel, a tight anatomic space just under the flexor retinaculum. Division and release of the retinaculum serves a purpose analogous to that served by carpal tunnel release in the hand. In diabetic patients with forefoot ulcers, this procedure can reduce ulceration. Although tarsal tunnel release evolved as a means of treating neuropathic foot pain, it has been shown, in properly selected patients, to prevent foot ulceration by restoring foot sensibility.³⁰

A solid grasp of the structural anatomy of the lower-extremity vasculature is, of course, essential for surgeons treating patients with leg ulcers. Perhaps even more important, however, is an understanding of precisely how the various blood vessels are related to one another, as well as to the specific structures and areas that they supply. Such an understanding may be facilitated by

Table 3 Angiosomes (Vascular Territories) of Foot

Artery	Vascular Territory Supplied
Anterior tibial artery	Anterior aspect of lower leg, anterior ankle
Dorsalis pedis artery	Dorsum of foot
Peroneal artery Anterior perforating branch Calcaneal branch	Posterolateral aspect of lower leg Upper portion of lateral ankle Lateral plantar heel
Posterior tibial artery Calcaneal branch	Posteromedial aspect of lower leg Medial heel
Lateral plantar artery	Lateral aspect of plantar foot, plantar forefoot (usually extends to hallux)
Medial plantar artery	Medial instep region between heel and forefoot

viewing the blood supply to the foot and lower leg through the concept of angiosomes—that is, the specific vascular beds supplied by major named arteries. Angiosomes have been well described by Taylor,³¹ and their application to the foot has been advanced by Attinger and associates.^{32,33} The significance of the angiosome concept (which is frequently employed by plastic surgeons but is less familiar to other surgeons) lies in its ability to relate the major nutritive blood vessels to the surface anatomy, to the physical examination, and to the planning of operations. The lower extremity has several angiosomes [see Table 3]. Most of them reach watershed status in the ankle and foot, which explains why most ischemic ulcers occur below the midcalf area.

Although the major leg arteries supply distinct angiosomes of the foot and ankle in a consistent manner [see Figures 1 through 5], they are not immutably segregated from each other and in fact are linked by anatomically reliable connections. The links are the so-called choke vessels, which represent anastomotic connections between adjacent angiosomes. The significance of these choke vessels is twofold: first, they serve as an alternate route of blood flow from one angiosome to another in situations of low or impaired flow (e.g., stenosis), and second, they can be used by the surgeon in designing flaps and predicting healing status. It is important to be aware of these connections when treating a wound that may be burdened by local ischemia. As an example, the heel is supplied by two distinct angiosomes, the calcaneal branch of the posterior tibial artery and that of the peroneal artery, and native anastomoses exist between these two areas. If there is a necrotic wound in the plantar heel, it follows that both vascular trees must be diseased, because if only one were diseased, the native anastomoses between the two angiosomes would prevent the ulcer from forming.³³ As another example, connections normally exist between the anterior perforating branch of the peroneal artery and the anterior tibial artery at the lateral ankle. The astute surgeon can exploit this knowledge to map blood flow to distinct areas of the foot for the purposes of diagnosis and subsequent reconstructive flap design.^{32,33} By alternately compressing flow above and below the arteries, the surgeon can determine whether retrograde blood flow to an adjacent angiosome is occurring (through choke vessels). If it is not, that area should not be used for a distally based flap.

Clinical Evaluation and Investigative Studies

When confronted with a lower-extremity ulcer, the surgeon should proceed with the physical examination in a systematic, goal-directed manner. It is important to recognize those presentations

that call for emergency triage in the operating room. One such surgical emergency is a leg or foot wound that is also acutely ischemic. The priority in this situation is prompt revascularization of the leg. Another emergency is a gangrenous leg or foot wound that has overcome host resistance and is associated with ascending sepsis (often, necrotizing fasciitis). The priority in this situation is urgent debridement of the devitalized and infected tissues; in some cases, emergency guillotine amputation may be required. All other wounds are not emergencies and may be evaluated in a more systematic fashion. Each patient encounter should commence with a vascular examination. Diligent evaluation of the blood supply to the lower

Figure 1 Shown are the angiosomes of the anterior tibial artery and the dorsalis pedis artery.

Figure 2 Shown is the angiosome of the peroneal artery, along with the angiosomes of the anterior perforating branch and the calcaneal branch.

blood pressure cuff. As many as 30% to 40% of diabetic leg ulcer patients have falsely elevated ABIs that may mask an ischemic foot. In nondiabetic patients, an ABI lower than 0.5 mandates further imaging to search for possible stenosis or occlusion. In diabetic patients, measurement of the toe-brachial index (TBI) may be more useful.^{36,37} Because toe vessels are less frequently affected by atherosclerotic disease (pedal sparing), toe pressures are a more reliable diagnostic tool in this setting. A value lower than 30 mm Hg is indicative of ischemia.

In addition, measurement of the transcutaneous oxygen tension (P_{tcO_2}) is extremely helpful, particularly for patients with distal foot ulcers that may be prone to impaired oxygenation from local microangiopathy. P_{tcO_2} levels are also useful for evaluating the response to therapy and may help predict healing.^{13,38} Ischemia is present if the P_{tcO_2} is lower than 30 mm Hg.

Figure 3 Shown is the angiosome of the posterior tibial artery, along with the angiosome of the calcaneal branch.

extremity is essential in all patients with problem wounds. Comparison to the contralateral leg (if present) can be very useful. The first step is to assess the appearance of the leg, evaluating such data as color, skin texture, swelling, and temperature. Pulses are then palpated, as is capillary refill. If impaired tissue perfusion seems to be a possibility, these examinations should be supplemented with more objective diagnostic studies. As a practical matter, pulses in the foot are notoriously difficult to evaluate: different examiners not infrequently report different findings. Among other variables, the skin in the area may be edematous or fibrotic, hindering assessment. A pulse may appear diminished to one examiner but normal to another. Finally, blood flow may be impaired distal to the ankle, where pulses are typically evaluated. Various modalities are available for diagnosis in this setting; the following are among the more commonly employed and useful ones.^{34,35}

Determination of the ankle-brachial index (ABI) is generally helpful, except in diabetic patients. The reason for the exception is that diabetes is associated with increased calcification of the arterial wall in the calf, which renders the vessel incompressible by the

Figure 4 Shown is the angiosome of the lateral plantar artery.

If the quality of the flow is questionable, either a formal noninvasive Doppler evaluation or angiography should be performed. If arterial inflow is found to be inadequate, the patient should be referred to a vascular surgeon—ideally, one who is trained in endovascular techniques and distal revascularizations.

A careful neurologic examination should be done to evaluate sensation and motor function. This is a particularly crucial in the management of a compartment syndrome (whether traumatic or resulting from a vascular accident). In diabetic patients and those with neurologic disorders, the neurologic examination can determine whether neuropathy contributed to the development of the wound. Lack of protective sensation is diagnosed by tonometry: if the patient is unable to feel 10 g of pressure applied by a Semmes-Steinstein 5.07 monofilament, significant sensory loss has occurred. This sensory loss prevents patients from registering skin damage that occurs as a result of excessive local pressure from a prolonged decubitus position; tight shoes, clothes, or dressings; biomechanical abnormalities; or the presence of foreign bodies. In neuropathic patients with biomechanical abnormalities, the repetitive trauma inherent in normal ambulation leads to ulceration as a consequence of the high focal plantar pressures generated during walking.

Management: General Principles

Current surgical education includes little formal training in the proper management of wounds. Accordingly, it is worthwhile to address some of the basic elements of wound care.

PREPARATION OF WOUND FOR HEALING OR RECONSTRUCTION

The first step in wound management is to establish a clean and healthy base. This can be accomplished in a variety of ways. A wound with a heavy eschar and grossly contaminated tissue requires surgical debridement in the OR [see Surgical Treatment, Surgical Debridement, *below*]. A wound with a mild amount of slough may be effectively debrided with an enzymatic dressing or even a water jet device (e.g., Waterpik; Water Pik, Inc., Fort Collins, Colorado). All wounds (except arterial and, usually, vasculitic ulcers) should be debrided down to healthy tissue. This measure resets the clock, so to speak, by effectively converting a chronic wound into an acute one. Because debridement is such a basic step, it tends to be underappreciated, even by surgeons.

There are three components of a leg ulcer that must be removed by means of debridement: (1) biofilm and bacteria, (2) callus, and (3) nonviable tissue.³⁹⁻⁴¹ Whereas the role of bacteria in wound infections has long been recognized, it is only comparatively recently that the contributions of biofilm to wound chronicity have come to be appreciated.^{10,42} Biofilm consists of a sessile community of multiple bacteria species encased by a protective carbohydrate-rich polymeric matrix that is resistant to antimicrobial and immune cell penetration.⁴³ Most wounds are in fact colonized by bacteria that set up residence in a biofilm. Unfortunately, biofilm is exceedingly tenacious and readily reaccumulates after debridement. Thus, proper dressing care consists of dressings that both treat the wound and minimize biofilm accumulation.

Bacteria, whether free-floating or (more commonly) incorporated within a biofilm, are extremely detrimental to wound healing,

Figure 5 Shown is the angiosome of the medial plantar artery.

particularly when they reach the level of critical colonization.⁴⁴ Wounds may be classified as contaminated, colonized, critically colonized, or infected.⁴⁵ These classifications are useful in that they detail the relation between the bacteria and the patient (or host) and define the level of bioburden (i.e., the cost exacted by bacteria from the resources of the wound and the patient). All wounds are contaminated to some degree, either by skin flora or by environmental pathogens. It is likely that this level of bacterial contamination stimulates wound repair mechanisms by upregulating the inflammatory response. When the contaminating bacteria begin to proliferate, the wound is said to be colonized; however, there is still no overt reaction by the host at this point. When the proliferating bacteria begin to overcome host responses, the wound is said to be critically colonized. Finally, when the wound provokes an inflammatory reaction by the host to the proliferating bacteria, the wound is said to be infected. It is important to keep in mind that the host's inflammatory reaction can contribute as much to a wound's failure to heal as the bacteria themselves do [see Figure 6].^{2,46} Judicious

use of antibiotics, adequate debridement, and proper dressing choices can decrease bacterial numbers and reduce the competition for nutrients and resources occurring in wounds contaminated by bacteria.⁴⁴ As noted (see above), because most leg wounds are found in ischemic, aged tissue beds, reduction of the bioburden can enable healing by restoring the balance between bacterial numbers and the nutrients available to healing cells.

Callus is formed in response to repetitive high pressure, usually over bony prominences on the foot. Once formed, it can further concentrate and propagate this excessive pressure on the underlying tissues. In addition, the grossly hyperkeratotic skin can act as a functional barrier to dressings and to migrating healthy keratinocytes. Therefore, callus should be removed whenever present. This can be done with a sharp, heavy scissors or a No. 10 blade; anesthesia is not required.

Nonviable tissue plays no necessary role in ulcer healing. The old paradigm of allowing wounds to heal under an eschar is obsolete, and the importance of moist healing is now appreciated.

AMOUNT OF EXUDATE	TYPE OF DRESSING
None or Minimal	Film, Hydrogel
Mild	Hydrocolloid
Moderate	Alginate
Large	Foam, Other
Copious	NPWT

Figure 7 The type of dressing used for a wound is influenced by the amount of exudate present.

Eschars are nature’s biologic dressings, but in the settings of ischemia, diabetes, and certain other diseases, they can give rise to an excessively proinflammatory state characterized by high levels of free radicals and proteases.^{47,48} This proinflammatory state is hostile to healing, propagates cellular damage, and competes with host cells for scarce resources. Therefore, all eschar and nonviable tissues should be removed.

DRESSINGS AND ADJUNCTS TO HEALING

There are literally thousands of dressings on the market. The vast majority of these products have not yet been proved superior to gauze by well-designed, randomized, prospective, controlled clinical trials. This is not to say that they are useless; rather, it is to remind practitioners that there are intense commercial and clinical needs driving the marketing of wound dressings and that claims of efficacy should therefore be taken with a grain of salt. Most wounds will heal, even if the dressing does not have the efficacy claimed. The main goal of a dressing should be maintenance of a moisture level optimized to facilitate wound healing and encourage autolytic debridement.⁴⁹ Other goals include coverage of the wound (to prevent soilage) and delivery of antimicrobial agents (e.g., silver ions and cadexomer iodine). It is important to use the proper dressing for a given wound [see Figure 7]: if the wound dries out, the healing cells may die, and if it is too moist, bacterial overgrowth and skin maceration may result.

Autolytic debridement consists of facilitating the body’s removal of dead tissue and cells by providing an optimal (usually moist) wound environment. If a proinflammatory eschar is prevented from forming (by preventing biofilm accumulation and minimizing slough buildup and desiccation), the body’s own phagocytic mechanisms will gradually remove the impediments to healing. Wound healing will then follow a normal trajectory. Film dressings, hydrogels, and other moist products may be used to accomplish autolytic debridement.

A particularly effective debridement method that is enjoying a resurgence in popularity is the use of maggots.^{50,51} Because of the strong propensity of these organisms for ingesting dead tissue, this form of debridement is extremely selective. The maggots are placed on the wound and contained within the wound’s confines with net gauze; every 2 to 3 days, they are changed. Although maggots cause considerable social discomfort among caregivers, they are actually a very good option for wound bed preparation in patients with severe comorbid conditions, and in most cases, they are remarkably well tolerated. Candidates for maggot debridement include patients with severe limb ischemia who are not candidates

for surgery or anesthesia or whose wounds might be exacerbated by surgical trauma (e.g., patients with infected wounds and critical limb ischemia).

Enzymatic debridement employs proteolytic agents to break up the proteinaceous debris that accumulates within the wound. These agents are efficacious in breaking up limited amounts of necrotic tissue but do not penetrate eschar very well. Some tenderness is associated with their use.

The role of ultrasonography in wound debridement is being actively investigated. Currently, the MIST Therapy System (Celleration, Inc., Eden Prairie, Minnesota) is approved and reimbursed as a noninvasive debridement device.^{52,53} Although the mechanism of action is still not fully known, it is likely that the device works by breaking up biofilm; it may also have other cellular effects, such as stimulation of blood flow and direct cell stimulation.

Negative-pressure wound therapy (NPWT) is an important addition to the surgeon’s armamentarium. It acts to encourage granulation tissue ingrowth through multiple mechanisms—in particular, edema reduction, mechanotransduction, and removal of proteases.^{54,55} NPWT must be employed properly: it should ideally be applied to relatively clean wounds, should be applied very cautiously to ischemic wounds, and should not be applied at all to wounds with known malignancies. It is useful in converting emergency wounds for which flap coverage is required into wounds that can be treated more simply. Care must be taken not to overuse or misuse NPWT. For example, it should rarely be used before the wound is completely closed. At some point, the wound will be small enough that it either can heal with simpler, less expensive dressing changes or can be closed primarily or with a simple skin graft.

Hyperbaric oxygen (HBO) is a useful, albeit often maligned, wound care modality. The lingering suspicion surrounding its use today results not from lack of utility but from inappropriate use in the past. The benefits of HBO include improved cellular oxygen delivery, maintenance of cellular metabolism through preservation of cellular adenosine triphosphate (ATP) levels, increased angiogenesis, reduced oxidative stress from persistent ischemia, increased perfusion, increased collagen synthesis and fibroblast function, and reduced infection.⁵⁶ It is likely to be of particular value in patients with irradiated ulcers or diabetic feet. Broadly speaking, HBO will be useful if an increase in tissue P_{iO_2} can be demonstrated when the patient is given supplemental oxygen^{57–59}; typically, an increase of 10 mm Hg suggests that HBO may be worth trying. HBO does require a facility with dedicated staff, and there are risks associated with its use, some of them life-threatening.

Another option is a tissue-engineered dressing, such as Apligraf (Organogenesis Inc., Canton, Massachusetts), which is a cultured bilayered dressing of human foreskin-derived fibroblasts and keratinocytes grown on a bovine collagen matrix.⁶⁰ Because the cells are not autologous, they are not ultimately incorporated into the wound but may persist within it for several weeks. Like the cells in a skin graft, the cells in Apligraf appear to produce a panoply of growth factors, which accounts for the efficacy of this dressing in ulcer care. In addition, Apligraf is easy to apply. Apligraf is approved for use in both diabetic foot ulcers and venous stasis ulcers, and it is widely used off label in other types of wounds.^{61,62} Another useful tissue-engineered dressing is Integra Bilayer Matrix Wound Dressing (Integra, Plainsboro, New Jersey), an acellular scaffold of glycosaminoglycans and collagen. Integra serves as a three-dimensional matrix within which cellular ingrowth takes place, and it eventually becomes completely incorporated within a wound or defect; once incorporated, it is covered with a thin auto-

logous skin graft. Integra may be used to resurface exposed bone, tendon, and orthopedic hardware, and in some case, it may render a flap procedure unnecessary.⁶³ One caveat to the use of tissue-engineered dressings is that they must be applied only to wounds that are free of infection or significant bacterial colonization. Another drawback is that they are expensive and thus must be used strategically.

SURGICAL TREATMENT

Surgical Debridement

Debridement is not always a surgical procedure. In fact, the majority of leg ulcers can be effectively managed with nonsurgical debridement, typically in the form of dressing changes or wound ointments that encourage the body to heal (see above).

Often, however, surgical debridement is the best option. It is extremely effective, but it is also the most invasive type of debridement, the most likely to cause bleeding, and the most painful (except when done in an insensate foot, such as that of a diabetic patient). Whether performed in the OR or in the clinic, the goal of debridement is to remove all nonviable, infected tissue and reach bleeding tissue or viable fat, tendon, or fascia. The benefits of a well-performed debridement are tremendous, including excision of callus (which augments pressure during ambulation), removal of biofilm and necrotic tissue (which amplifies the inflammatory host response and competes with the healing tissue for oxygen and nutrients),⁴⁴ conversion of a chronic wound to an “acute” wound, stimulation of cell proliferation (by injuring healthy cells and releasing growth factors into the wound environment), and ridding the wound bed of senescent cells and chronic wound fluid (which has been demonstrated to contain growth factor–neutralizing proteases).^{64,65}

A novel form of surgical debridement is hydrosurgery (VersaJet; Smith & Nephew, Hull, United Kingdom), which involves using a “water knife” for selective removal of infected or devitalized tissue.⁶⁶ It is expensive, but its benefits are formidable, and it is likely to see expanded use in the future.

Reconstruction with Grafts or Flaps

The optimal closure technique for a given wound depends as much on the wound type as on the patient. In evaluating different reconstructive options, plastic surgeons often rely on the concept of a reconstructive ladder (or elevator). In general, the simpler or less invasive techniques are considered first (representing the lowest rungs on the ladder). If simpler techniques prove unsuitable or inadequate, decision-making proceeds to consider increasingly complex and morbid options (successively higher rungs), culminating in microvascular free flaps or transfers (the top rung). As may be apparent, this schema is simplistic and does not always apply to the lower extremity, where often the first choice (or the only real choice) is a complex free flap. The concept of the reconstructive elevator is more useful in the leg, where the surgeon can directly choose the option best suited for a particular wound or defect.⁶⁷

Skin grafts are often used to close shallow wounds or wounds in the non–pressure-bearing instep of the foot. If a decision is made to close a foot or leg wound surgically, several principles should be kept in mind. The main one is that the simplest solution is usually, but not always, the best. It is important to leave room for creativity in the use of flaps. There are numerous different local flaps that are extremely useful (see below). Most wounds do not require microsurgical flaps, but occasional ones do benefit from microsurgery. There are also important issues related to orthopedic

management of foot wounds, particularly in diabetic patients, that must be taken into account.

Three main types of flaps are employed in the lower extremity: local random-pattern flaps, local pedicled flaps, and free tissue transfers [see 3:3 *Open Wound Requiring Reconstruction* and 3:7 *Surface Reconstruction Procedures*].

Local random-pattern flaps Local random-pattern flaps include such flaps as Z-plasties, advancement flaps (e.g., V-Y), rotation flaps, and transposition flaps.²⁴ These are extremely useful for closing small defects of the foot. One limitation to their use is the tautness of the skin in this area, which limits flap mobility. With imaginative design and careful execution, local random-pattern flaps can be employed for any small foot wound.

Local pedicled flaps Local pedicled flaps are employed for coverage in both the leg and the foot, especially for closure of larger foot wounds and deeper wounds that expose bone, capsule, or hardware. They are reliably based on axial vessels, typically branches of angiosomes. The following are among the more commonly used local pedicled flaps.^{68,69}

1. **Gastrocnemius flap.** This flap is used to cover proximal defects in the knee and the proximal third of the leg. As a rule, half the muscle is used. The medial gastrocnemius is generally preferred unless the wound or defect is laterally based.
2. **Soleus flap.** This flap (preferably from the medial portion of the muscle) is used for coverage of deep wounds in the middle third of the leg.
3. **Reverse sural fasciocutaneous flap.** This flap is an option for defects of the lower leg and ankle.⁷⁰ A delayed procedure is prudent in patients with impaired or uncertain vascular status or comorbid conditions (e.g., diabetes or renal failure).⁷¹ Some surgeons will not use a reverse sural flap, because the donor site in the proximal calf must be covered with a skin graft, which could hinder the wearing of a prosthesis if a below-the-knee amputation proves necessary. This limitation can, however, be addressed by using an anteriorly based skin flap for the amputation to cover the calf muscles. The reverse sural flap is an extremely versatile one that usually covers heel defects well, particularly in patients with tenuous vascular inflow, without requiring microsurgical skills or facilities.
4. **Other flaps for the leg.** Other options in the leg include wide-based adipofascial flaps that can be rotated to cover a defect and skin grafted to achieve cutaneous coverage.^{72,73} These do not have a reliable axial blood supply, particularly in patients with vascular disease⁷⁴; they mostly have a random pattern of blood flow.
5. **Medial plantar flap.**⁷⁵ This flap is particularly well suited to coverage of calcaneal defects. It brings thick, glabrous skin that will resist breakdown and the shearing forces affecting the heel. If the medial plantar nerve is incorporated, the flap will be sensate. The medial plantar flap can also be advanced distally into the forefoot if necessary, typically in the form of a V-Y advancement flap.
6. **Abductor digiti minimi flap.**⁶⁹ This flap is best used for small defects of the lateral ankle and heel, particularly wound dehiscences after orthopedic procedures. It is dissected in a distal-to-proximal direction and transposed to cover proximal defects. The donor site is closed primarily and requires a skin graft for coverage.
7. **Abductor hallucis brevis flap.** With this flap, as with the abductor digiti minimi flap, the dominant arterial pedicle is situated

rather proximally, allowing the distal abductor hallucis brevis to be dissected completely free and rotated to cover defects of the medial heel and ankle. Again, a skin graft is required for coverage of the donor site.

8. Extensor digitorum brevis flap. This flap is a multipennate flap consisting of several slips of muscle that inserts via tendons on the second through fifth toes. It is used for coverage of dorsal foot and ankle defects.

Other useful muscle flaps include the flexor digitorum brevis flap (for heel defects) and the flexor digiti minimi musculocutaneous flap.

Free tissue transfers The rich variety of flaps available for coverage of leg and foot wounds has led to a decline in the use of microsurgical free flaps in the lower extremity. The development of NPWT has also contributed to the declining need for free flaps, in that many wounds are currently being downstaged with NPWT to enable eventual closure with a technique farther down the reconstructive ladder. Nevertheless, there remain certain wounds in all areas of the leg and foot for which free flaps may still be useful or even preferable, such as large defects and wounds characterized by significant exposure of bone or hardware. Flow-through free flaps are also commonly used to achieve revascularization and wound coverage simultaneously. Occasionally, free flaps are used for wounds with venous insufficiency or lymphedema in an attempt to improve these conditions by restoring lymphatic channels or competent venous drainage. The free flaps used in the lower extremity may be either fasciocutaneous or muscle flaps. Most studies have not found either type of flap to be superior to the other for treatment of areas of infection. In general, however, fasciocutaneous flaps are preferred for wounds on the sole of the foot, which are exposed to pressure and shearing forces, whereas muscle flaps are preferred for deep wounds.

Amputation

On occasion, amputation proves necessary [see 6:20 *Lower-Extremity Amputation for Ischemia*].⁷⁶ Factors such as advanced age, uncontrolled diabetes, sepsis and gangrene, unreconstructable blood vessels, and renal failure are all associated with a higher risk of amputation. Nevertheless, a focused, multidisciplinary approach to wound care should be able to reduce amputation levels substantially and achieve limb salvage rates higher than 90%. Overall, the most frequently performed amputations are toetip amputations. Of these procedures, the most common is amputation of the tip of the great toe. This operation is done to treat the claw-type deformity seen in diabetic patients with an intrinsic-minus foot, whereby the toe becomes permanently flexed as a result of the pull of the flexor hallucis longus tendon. The tip amputation may have to be closed with a fishmouth-type incision or a V-Y advancement flap from the plantar surface. In addition, it may be necessary to advance the flexor hallucis longus tendon and perform a volar capsular release to minimize recurrence.

Amputations of the toe rays are frequently performed, most commonly in diabetic patients but also in patients with osteomyelitis of the metatarsal heads. Rebalancing the pull of the extrinsic tendons is crucial for preventing redistribution of the maladaptive forces to adjacent rays and subsequent propagation of serial ulcers in these areas. Therefore, the peroneus brevis and tibialis anterior insertions should be reattached to the cuboid or the cuneiform for proximal fifth and first ray amputations, respectively.²⁴

Most amputations of the foot are performed at the transmetatarsal level. Transmetatarsal amputation is a very useful pro-

cedure that preserves as much of the foot's length as possible while also maintaining a well-balanced walking surface with thick plantar skin. Fundamentally, it is a reconstructive procedure: the vascular supply to both the plantar and the dorsal flap must be ensured prior to closure, and the balance of the foot tendons must be addressed.⁷⁶ The plantar metatarsal arteries, which supply the plantar flap, must be kept intact by avoiding excessive undermining or indiscriminate use of the electrocautery. If the flap appears compromised after closure, the flap sutures should be released, and completion of the flap procedure should be delayed for several days to encourage increased neovascularization. NPWT may be used as a temporizing measure to bridge the wound before formal closure. After a transmetatarsal amputation, the triceps surae may be lengthened to compensate for the loss of ankle dorsiflexion that results from removal of the attachment points to the toe extensor tendons.²⁴

Management of Specific Types of Lower-Extremity Ulcer

In the early stages of management, it is important to focus on the patient's overall health status, with a particular emphasis on the presence or absence of sepsis. It is also vital to determine whether adequate vascularity is present to enable healing. Most wounds benefit from debridement, whether biologic (i.e., dressings and wound care) or surgical. At the same time, normalization of systemic derangements is undertaken. A decision is made whether to treat the wound surgically. In most instances, this does not have to be done right away. Surgical wound closure, when feasible, is best done after a period of optimization.

In addition to these considerations, which are common to all leg ulcers, there are aspects of care that are specific for different ulcer types. Accordingly, in what follows, I focus on specific care of the most prevalent types of leg ulcer—namely, those resulting from arterial insufficiency, those associated with diabetic neuropathy, those resulting from venous stasis, and those of inflammatory origin.

ULCERS RESULTING FROM ARTERIAL INSUFFICIENCY

Most arterial leg ulcers occur in the elderly. A nonhealing ulcer is one of the most common presentations of peripheral vascular disease, the incidence of which is highest in men older than 45 years and women older than 55 years. Modifiable risk factors for peripheral vascular disease include smoking, hyperlipidemia, hypertension, diabetes, and obesity.

In most instances, the diagnosis is suggested by the physical examination. Arterial leg ulcers generally occur in a stereotypical distribution that is well explained by the angiosome concept mentioned earlier [see *Anatomic Considerations, above*], most commonly developing over the toes, heels, and bony prominences of the foot. It is worth noting that a heel ulcer typically results if there is disease in the distributions of both the peroneal artery and the posterior tibial artery, as a consequence of the dual blood supply to the posterior heel from these vascular territories.³³ Ulcers in the toes result from the diminished distribution of blood to these terminal vascular beds. An ulcer in the setting of arterial insufficiency is a symptom of the decreased blood flow and may be associated with rest pain or claudication. The metabolic demands of intact skin are less than those of an open wound, but even so, the impaired blood flow renders the skin thin, atrophic, hairless, and dry in the affected extremity. Patients usually experience significant pain, which is relieved by dangling the leg over the bed at night. The ulcer has a sharply demarcated appearance, with a paucity of granulation tissue. The wound bed is pale or pink and typically

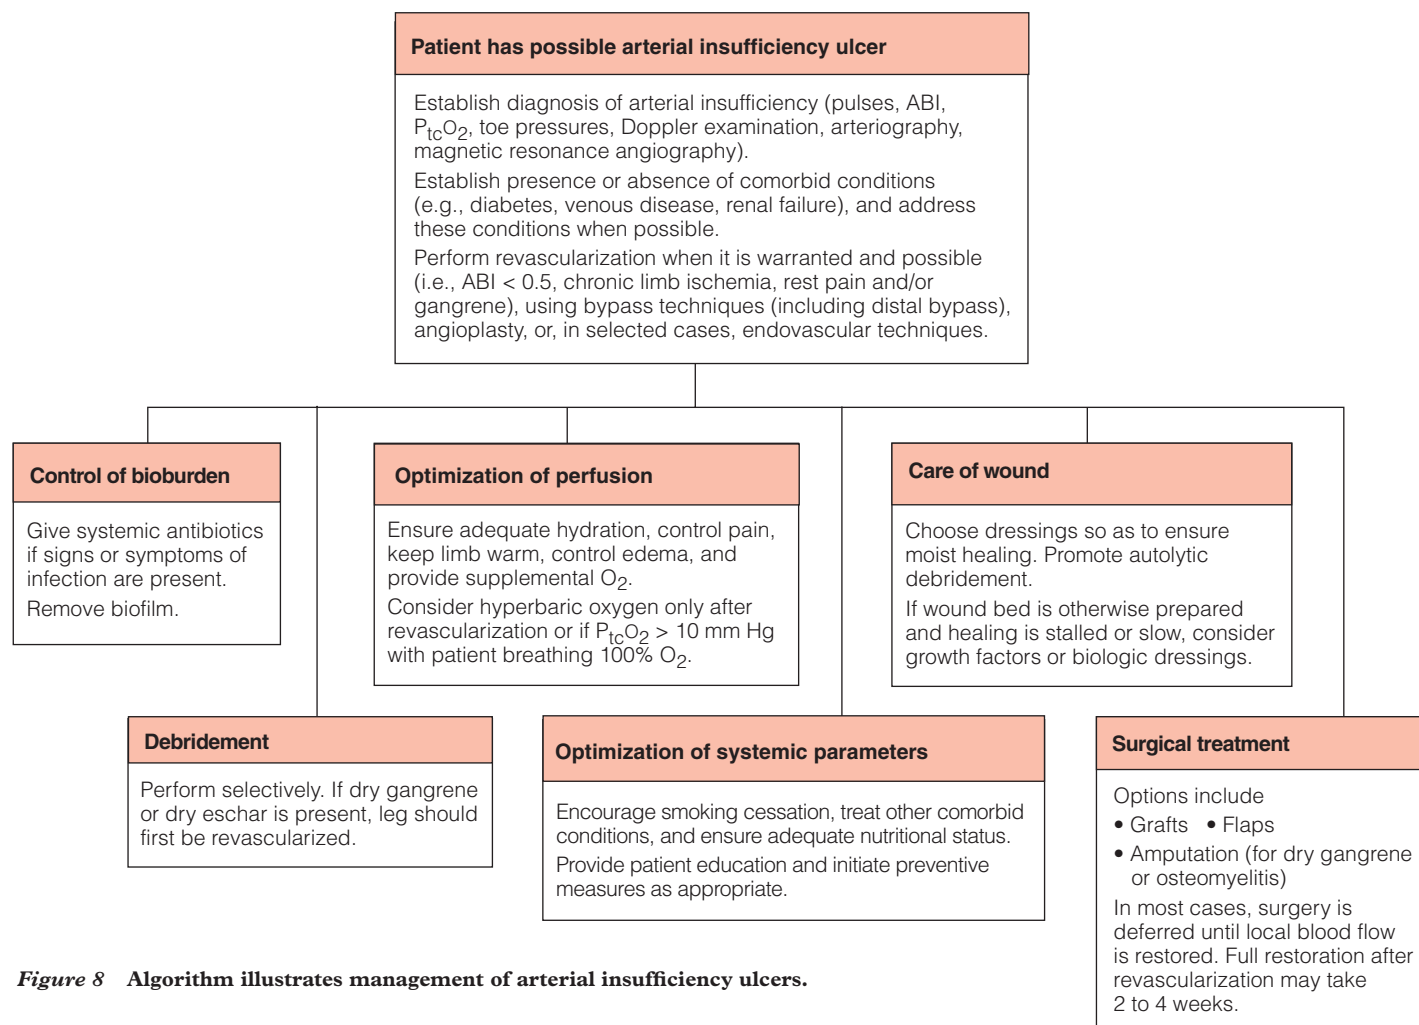

Figure 8 Algorithm illustrates management of arterial insufficiency ulcers.

lacks the red color associated with a hypervascular healing bed. Pulses are usually diminished. Any patient with decreased pulses at the ankle (signaling insufficiency of the dorsalis pedis, the posterior tibial artery, or both) should be referred for vascular studies. In practice, given the wide interindividual variation in the ability to palpate a pulse accurately, it is advisable to set a fairly low threshold for obtaining studies such as an ABI or a TBI. In general, arterial leg ulcer patients with an ABI lower than 0.9 or higher than 1.2 or with a P_{tc}O₂ lower than 30 mm Hg should be referred to a vascular surgeon.

Quite often, the etiology of an arterial leg ulcer is not purely ischemic but includes contributions from other conditions, such as diabetes, venous insufficiency, neuropathy, and renal failure. These ulcers of mixed etiology are particularly challenging to treat, and it is all too common to find a supposedly chronic wound whose chronicity actually resulted from an earlier failure to establish the leg's vascular status.

At the cellular level, the cause of an arterial ulcer goes beyond the simple lack of sufficient oxygen supply to a cell. For example, it is known that sublethal ischemia is much more detrimental to aged cells and diabetic cells than to young cells.^{77,78} Lack of ATP and inadequate clearance of metabolites result in poor healing and aberrant inflammation. Because healing is an anabolic process, much more energy is needed for healing than for tissue maintenance and homeostasis. The persistence of noxious metabolic byproducts that are not cleared by the circulation may be a cause of the pain commonly associated with these wounds.⁷⁹

At the tissue level, chronic regional ischemia results in atrophic changes to the skin and soft tissues. The terminal nature of the vascular tree in the foot, with the distal foot and toes being less well perfused than the calf and thigh, along with the effects of gravity and the rigors of ambulation, means that these downstream areas bear the brunt of the effects of upstream atherosclerosis. In the setting of a minor injury, the atrophic skin is more liable to progress to a full-thickness injury in the distal foot and toes than in more proximal locations and, indeed, is more likely to tear in the first place. As mentioned (see above), synthesis of new tissues and deposition of matrices and collagen, along with collagen crosslinking, are necessary for ulcer healing. These are all rate-dependent processes, with oxygen being the necessary variable. Unfortunately, the impaired tissue perfusion means that the ulcer bed will not receive an adequate supply of oxygen and nutrients to support tissue growth. In addition, because oxygen is necessary for the neutrophil burst, arterial ulcers are especially predisposed to infection.¹¹

These considerations help explain the typical appearance of ulcers resulting from arterial insufficiency: the sharply demarcated boundaries (attributable to the "on/off" borders between the defect and unwounded skin, with a minimal healing interface); the dry wound beds, with minimal transudate and exudate; the pale granulation tissue, indicative of a hypovascular state; the changes in the appearance of the surrounding skin (see above); and the reduced capillary refill time.

In the treatment of a wound with an arterial component [see Figure 8], the *sine qua non* is revascularization: a wound typically

will not heal if the leg’s blood supply is not improved.¹¹ Therefore, the urgent decision to be made at this point is whether revascularization is feasible. It should be kept in mind that the decision as to whether an extremity is a candidate for revascularization should be made only by a vascular specialist who is comfortable with or has access to newer modalities and procedures (e.g., distal bypasses and endovascular techniques). Noninvasive means of revascularization are useful in high-risk patients.

After revascularization, there is a lag phase before the ischemia is reversed in the distal leg and foot. Typically, a rise in P_{iO_2} is seen 1 to 2 weeks after surgical revascularization and is delayed after angioplasty.¹⁵ In patients with foot ulcers, foot pulses must be restored if the ulcers are to heal. The wound must be managed during the weeks after revascularization, and indeed for months to years afterward. It should be noted that techniques associated with lower long-term patency rates can nevertheless be useful if they enable healing of an open wound or amputation site. Once the ulcer is healed, the likelihood that a new wound will develop in the area diminishes (because of the lower energy requirements of healed skin in comparison with those of a healing wound).

Any significant comorbid conditions, such as diabetes or venous stasis disease (see below), should be addressed. Steps must also be taken to prevent or control infection, which can cause rapid deterioration in an arterial ulcer. If signs of local or systemic infection are noted, treatment with systemic antibiotics should be initiated promptly. Unless grossly infected tissue (e.g., wet gangrene) is present, it is best to defer debridement until the vascularity of the area is ensured: debridement while the blood flow to the area is still impaired may promote further ischemia and lead to the formation of a larger ulcer.¹¹ Dressings applied to ischemic ulcers typically must have moisture added in the form of hydrogels as the hypovascular wound bed desiccates. An enzymatic dressing can also be useful for gentle debridement of nonviable tissue. Systemic factors (e.g., global hypoxia, enhancement of cardiac output, pain control, and warmth) are important as well. In patients who respond to an oxygen challenge, HBO should be considered and offered if available; however, it should not be employed in place of surgical revascularization if the latter is an option.

Final surgical treatment, in the form of flaps or skin grafts, is deferred until blood flow is ensured. Occasionally, it is possible to perform what is termed extended limb salvage, wherein a bypass graft to the leg is performed at the same time that a microvascular free flap is used to cover a large defect.^{80–82} With advances in wound care products and the introduction of NPWT, however, most procedures can be staged. Flap procedures are typically undertaken after a period of days to weeks, once the oxygen supply is restored.

These patients are nevertheless at high risk for amputation, typically as a consequence of progressive atherosclerotic disease. Patients with unreconstructable peripheral vascular disease (particularly common in the setting of renal failure) or extensive tissue loss or gangrene usually require a major amputation. Even after the amputation, attention must be paid to the vascular status of the amputation site. If the blood flow to the skin has not been ensured, the amputation incision will be prone to breakdown and necrosis. In fact, as many as 25% of patients who undergo surgical revascularization experience a postoperative wound complication in the surgical incision. This finding underscores the points that a revascularized limb usually is still ischemic and that the surgical procedure must be done meticulously and with careful handling of soft tissue. Application of the angiosome concept can be extremely useful for determining the optimal amputation level and assessing the potential for healing.³²

DIABETIC ULCERS

There is a growing tendency to misapply the term diabetic foot ulcer. Many practitioners use this term to describe any wound that occurs in the leg of a diabetic patient, but strictly speaking, it refers only to a neuropathic plantar ulcer that originally results from pressure necrosis. Diabetic patients also have ischemic wounds and venous insufficiency ulcers, but these lesions are not true diabetic foot ulcers. It is important to keep in mind that diabetic foot ulcers may have several different presentations. For example, some are due solely to neuropathy, whereas others are due to ischemia in conjunction with neuropathy. Diagnosing a diabetic foot ulcer is straightforward; however, evaluating the vascular supply to the foot and determining how much neuropathy and functional microangiopathy contribute to the wound’s failure to heal are not always so straightforward. Evaluation of the diabetic foot is addressed in greater detail elsewhere [see 6:7 *Diabetic Foot*].

Currently, two diabetic foot ulcer classification systems are widely used, the Wagner system and the University of Texas (UT) system [see Table 4].^{83–85} At present, the UT system appears to be a better predictor of ultimate wound and foot outcome⁸⁶ and is more widely used in wound centers. A major shortcoming of the Wagner system is that the presence of ischemia is not a part of early-stage ulcers.

The pathology of diabetic foot ulceration is multifactorial. Chronic hyperglycemia leads to advanced glycosylation end products and crosslinking of proteins, eventually resulting in foreshortening of tendons. Relative ischemia (particularly in the vasa vasorum), coupled with the glycosylated protein buildup, leads to sensory and autonomic neuropathy. The autonomic neuropathy leads to anhidrosis and ultimately to fissuring, which affords bacteria a means of entry through the skin. In addition, it leads to hyperkeratosis, which increases the pressure over pressure points and

Table 4 Staging Systems for Diabetic Foot Ulcer

Wagner classification system	Grade 0: impending skin lesion, presence of predisposing bony deformity, or healed ulcer
	Grade 1: superficial skin ulcer that does not involve subcutis
	Grade 2: full-thickness ulcer that exposes bone, tendon, ligaments, or joint capsule
	Grade 3: full-thickness ulcer with presence of osteitis, osteomyelitis, or abscess
	Grade 4: gangrenous digit
	Grade 5: gangrene severe enough to necessitate foot amputation
University of Texas diabetic foot wound classification system	Grade I-A: noninfected, nonischemic superficial ulceration
	Grade I-B: infected, nonischemic superficial ulceration
	Grade I-C: ischemic, noninfected superficial ulceration
	Grade I-D: ischemic and infected superficial ulceration
	Grade II-A: noninfected, nonischemic ulcer that penetrates to capsule or bone
	Grade II-B: infected, nonischemic ulcer that penetrates to capsule or bone
	Grade II-C: ischemic, noninfected ulcer that penetrates to capsule or bone
	Grade II-D: ischemic and infected ulcer that penetrates to capsule or bone
	Grade III-A: noninfected, nonischemic ulcer that penetrates to bone or deep abscess
	Grade III-B: infected, nonischemic ulcer that penetrates to bone or deep abscess
	Grade III-C: ischemic, noninfected ulcer that penetrates to bone or deep abscess
	Grade III-D: ischemic and infected ulcer that penetrates to bone or deep abscess

reduces sensation in a foot already afflicted by sensory compromise. The tibial nerves may also be compressed.

The immune response is altered in diabetic patients. In particular, granulocyte function is impaired, and surgical debridements and advanced dressings are often required to minimize the effects of this deficiency. Moreover, signs and symptoms of infection are notoriously inaccurate and masked in this setting.

Blood flow is typically impaired in diabetic patients. The impairment usually develops at the macrovascular level as the result of accelerated atherosclerosis in the infrapopliteal area (in contrast to the peripheral vascular disease seen in nondiabetic patients, which mostly affects vessels in the thigh). This process underlies the phenomenon of pedal sparing, whereby the vessels in the foot and the ankle may be free of disease even though the more proximal vessels are not. Pedal sparing makes pedal bypasses and lower-leg bypasses possible, and therefore, revascularization is a mainstay of therapy for an ischemic diabetic foot. For years, many practitioners adhered to the concept of diabetic microvascular disease,⁸⁷ which suggested that performing revascularizations in diabetic patients was futile. This concept was based on anatomic studies that were later shown to be inaccurate.⁸⁸ It would be a mistake, however, to maintain that there is no microangiopathy in diabetic patients. In poorly controlled diabetic patients, a functional microangiopathy probably does exist, particularly in regard to ischemia-mediated angiogenesis.^{2,88,89} Indeed, numerous preclinical studies have demonstrated decreased growth factor expression in diabetic healing models. Accordingly, administration of growth factors (e.g., becaplermin) may be useful, provided that the other components of diabetic foot disease are being adequately addressed.⁹⁰

The so-called Charcot foot is the stereotypical end result of the decreased extensibility of the foot tendons (see above). The reduction in extensibility gives rise to a claw-type foot deformity, which causes the normal gait pattern and frequency to change in such a way as to redistribute the forces affecting the foot, usually leading to increased pressure over the metatarsal heads.⁹¹⁻⁹³ Given that the average ambulatory person takes about 10,000 steps each day, any alteration in the finely balanced gait pattern can have substantial deleterious consequences, including a diabetic foot ulcer.

Evaluation for vascular disease is mandatory in all patients with lower-extremity ulcers. It is of particular importance in diabetic patients, for several reasons. First, the incidence of peripheral arterial disease is much higher in diabetics than in the general population. Second, diabetics are more likely to have disease in the infrapopliteal distribution, and the frequency of arterial calcification in this area accounts for the unreliability of the ABI in these patients. Third, diabetics, unlike other patients with peripheral arterial disease, may not manifest claudication or rest pain, because of their polyneuropathy. In other words, just as diabetic patients may suffer from silent myocardial infarction, they may also suffer from critical ischemia that is not unmasked until after a surgical debridement or infectious episode.

Once the vascular status of the foot has been ensured or restored, the wound must be addressed [see Figure 9].¹³ The wound will heal, and remain healed, only if a diligent effort is made to address the variables that led to the development of the wound in the first place. These variables are present to differing degrees in different patients and thus make differing contributions to the formation of wounds. Consequently, there is no standard protocol that encompasses the care of all diabetic foot ulcers. Treatment of such wounds must be individualized, which is why it is best undertaken in a multidisciplinary fashion. The following are the general steps that should be taken to address the major causative variables,

though, as noted, their relative importance will vary from patient to patient.

First, pressure should be relieved (offloaded). Insensibility resulting from neuropathy plays a large role in pathogenesis, but so do altered biomechanics. For example, most forefoot ulcers occurring under the metatarsal heads result from an imbalance between the long and powerful extrinsic tendons and the smaller and functionally deinnervated intrinsic tendons, which causes the clawed posturing mentioned earlier (see above). There may also be loss or shifting of the plantar fat pad.⁹⁴ Pressure offloading can be achieved with orthotics or a total contact cast (the gold standard for pressure relief),⁹⁵⁻⁹⁷ but if the degree of deformity is severe enough, only an orthopedic or podiatric procedure will relieve the chronic pressure, permit healing, and minimize recurrences.

Second, the bioburden should be controlled. A diabetic patient is more likely to have a severe infection that necessitates antibiotic therapy. Because diabetic foot ulcers are pressure sores, there may be sufficient tissue loss to result in exposure of bone, infection, or, in some cases, osteomyelitis. For these reasons, wounds should be probed to determine whether they reach bone or joint capsules⁹⁸; deep space cultures are particularly useful for guiding antimicrobial regimens.⁹⁹

Third, neuropathy should be addressed if possible. Glycemic control or revascularization may result in some improvement. It may be possible to improve tibial nerve sensation by performing a tarsal tunnel release. Although the indications for tarsal tunnel release are still being investigated, the procedure clearly shows potential in selected patients.^{30,100,101} Offloading addresses the sensory deficit by other means. Patient awareness and diligent foot care and examination also play essential roles.

Fourth, the biomechanical derangements present should be addressed by other means besides simple offloading. Lengthening of the Achilles tendon can help take some pressure off the metatarsal heads.^{102,103} Whether this procedure is indicated can be determined by simply evaluating the degree of flexion possible at the ankle joint. Bony prominences and sesamoids may also be excised to achieve pressure relief.

Fifth, dressings should be tailored to the characteristics of the wound. Moist healing is the key. NPWT is extremely useful in the management of these wounds.

VENOUS STASIS ULCERS AND LYMPHEDEMA

Venous leg ulcers are the most common type of leg ulcer both in the United States and worldwide. Valvular incompetence is present in up to 10% of the population, with venous ulceration developing in 0.2%.¹⁰⁴ These leg ulcers arise as a result of sustained venous hypertension caused by longstanding venous insufficiency. More than 95% of them occur in the so-called gaiter region—especially around the medial malleolus, which is the region that sustains the greatest pressure increase from incompetent veins. Ulceration may be either discrete or circumferential. Ulcers occurring above the midcalf or on the foot are likely to have other causes.

The main risk factor for venous leg ulceration is advanced age, probably as a result of a lifetime of bipedal ambulation: as many as 4% of persons older than 65 years have a venous stasis ulcer. Another risk factor is a history of deep vein thrombosis (DVT); often, previous DVT has gone unrecognized. In about half of all cases, however, the deep venous system is normal, and the ulcers result from superficial venous insufficiency or from incompetence of the perforating veins connecting the superficial venous system to the deep venous system.¹⁰⁴ Incompetence of the valvular system within the perforating veins permits reflux into the superficial sys-

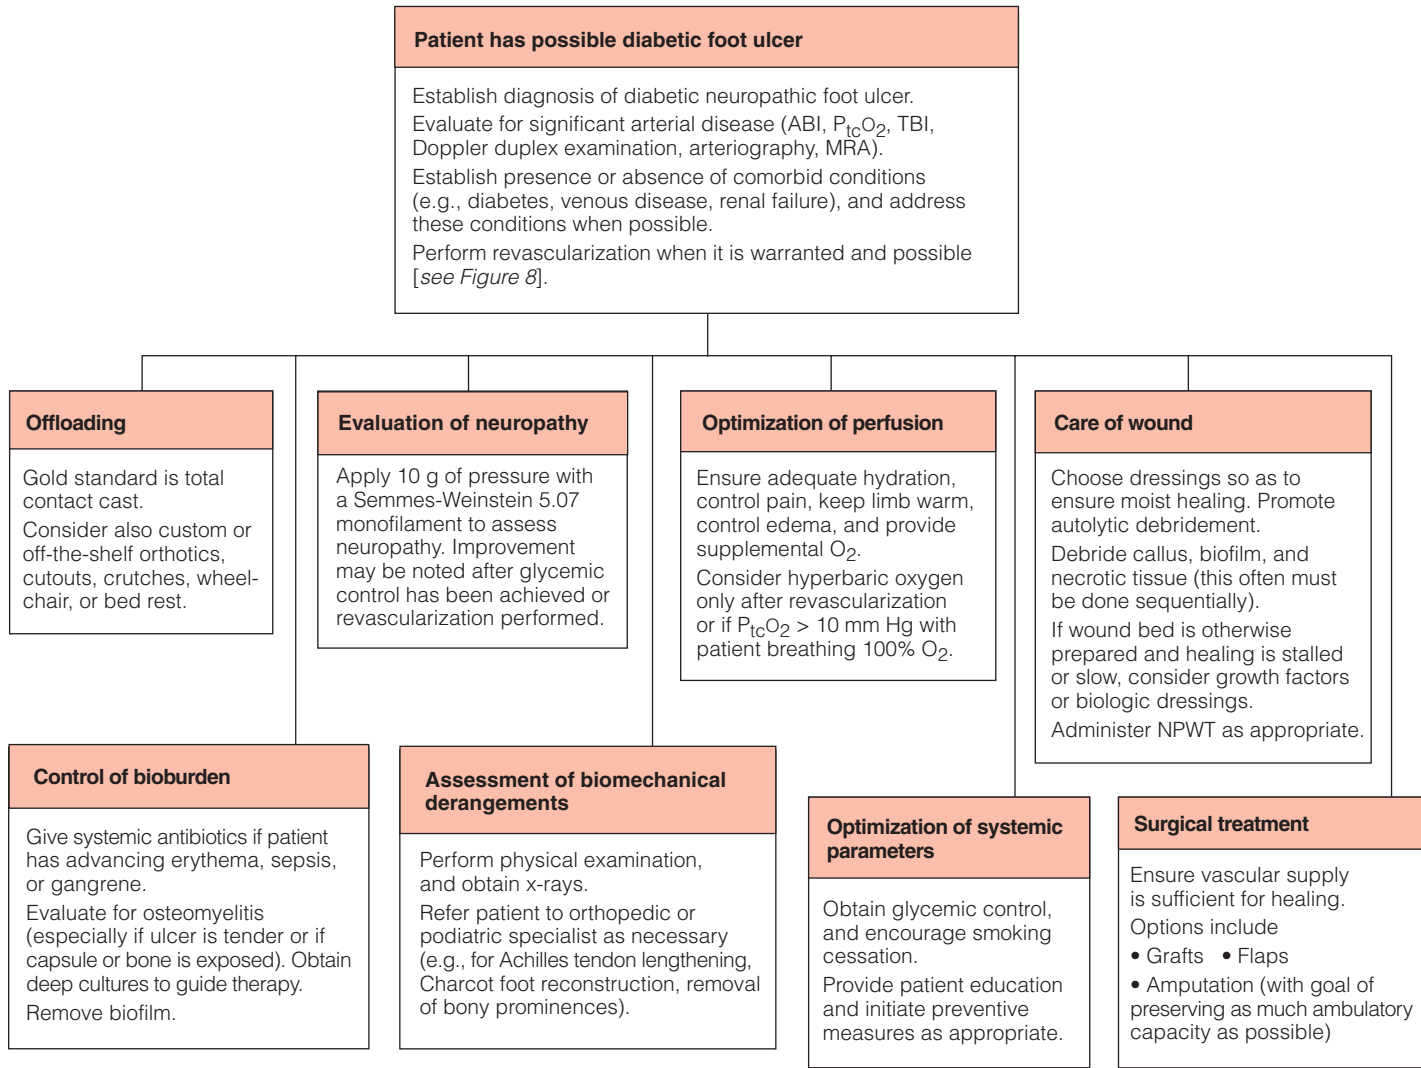

Figure 9 Algorithm illustrates management of diabetic foot ulcers.

tem.¹⁰⁵ Consequently, superficial venous pressure does not decrease during ambulation as the calf muscle pump propels blood to the heart but, rather, remains persistently high because of the reflux. Besides advanced age and a history of DVT, risk factors for venous leg ulcers include any condition leading to prolonged immobility, particularly wheelchair use, varicose veins, obesity, and fractures. For this reason, patients with thrombotic disorders (e.g., deficiencies of antithrombin III, protein C, or protein S) are also predisposed to venous stasis ulcers.

The pathogenesis is complex, and derangements are present at both the microcirculatory level and the macrocirculatory level.¹⁰⁵ Inflammation appears to play a significant role in ulcer propagation.¹⁰⁶⁻¹⁰⁸

Prompt and accurate diagnosis of a lower-extremity venous stasis ulcer is critical for subsequent treatment and wound outcome [see Figure 10].¹² The first and most important step is to rule out a contribution from arterial disease. As noted (see above), compression therapy is contraindicated when the ABI is lower than 0.7. In a diabetic or elderly patient—either of whom may have calcified arteries and an artificially elevated ABI (typically higher than 1.2)—a P_{tcO_2} higher than 30 mm Hg may rule out true ischemia. A TBI may also be useful in this setting; typically, it should be higher than 0.6.

An extremely useful modality for diagnosing venous stasis dis-

ease is color duplex ultrasonography, usually performed with external compression applied proximal to the leg. Duplex imaging is most useful for patients with complicated varicosities, varicose veins that have recurred after previous interventions, suspected deep venous disease, or small saphenous vein incompetence.

Compression dressings are the mainstay of care.¹⁰⁹ There are several types, including the Unna (Duke) boot, multilayer (i.e., three- or four-layer) compression systems, and intermittent pneumatic pressure systems. Compression stockings are categorized as class 1 (14 to 17 mm Hg pressure at the ankle, used for early varicose veins), class 2 (18 to 24 mm Hg pressure, used for mild edema and for patients with thin legs), or class 3 (25 to 35 mm Hg, used for chronic venous insufficiency and in larger legs and more involved edema). A class 3 compression system is required for proper treatment of a venous stasis ulcer.¹¹⁰

Graduated compression, in which the applied pressure is highest (about 40 mm Hg) at the ankle and tapers off to lower levels (about 20 mm Hg) below the knee, increases the hydrostatic pressure in the limb and concomitantly reduces the superficial venous pressure. This approach has been shown by several trials to be more strongly associated with healing than uniform compression is. Perhaps not surprisingly, high-compression bandaging systems and four-layer dressings have also been associated with faster healing of venous stasis ulcers.¹¹⁰ The key to using this modality is that com-

pression must be both sustained and graduated. The exact type of compression system best suited for each particular type of ulcer remains to be determined. In many instances, factors such as patient compliance, cost, and availability are the actual determinants of the type of compression employed in a given case.

The bioburden must also be addressed. Without proper and diligent care, venous stasis ulcers are almost invariably colonized by bacteria, most frequently by biofilm. Bacterial infection is common, with the main isolates being *Staphylococcus aureus*, *Pseudomonas aeruginosa*, and β -hemolytic streptococci. The exact role that biofilm and bacteria play in the pathogenesis of a venous stasis ulcer is still unclear, but it is likely to be a significant one: therapeutic measures that address the bacterial biofilm layer (e.g., low-frequency ultrasound and debridement) have been shown to yield substantial reductions in ulcer size when performed in combination with proper compression therapy. Topical antibiotics should be used judiciously in the treatment of venous leg ulcer infections; systemic antibiotics are indicated if there is evidence of cellulitis or progressive infection. If an area of cellulitis does not resolve with antibiotic therapy but there are no signs of progressive infection, the diagnosis of venous eczema should be entertained. Venous eczema is treated with topical steroids and emollients.

Systemic parameters should be optimized. Many patients are also obese, and leg ulcers in such patients are typically the most difficult to treat and the most likely to recur. It is difficult to achieve compression in these patients, and the presence of a dedi-

cated therapist may be helpful. Severe venous stasis associated with significant lymphedema may have to be treated with intermittent pneumatic compression.¹¹¹ Oral pentoxifylline and micronized purified flavonoid fractions may be given: these agents appear to reduce tissue inflammation and fibrosis in patients with venous stasis disease and hence may prevent ulcers from forming and help active ulcers to heal.^{112,113}

Debridement of the biofilm is frequently necessary. If the ulcer is small and relatively clean, debridement may be performed in the office with a local anesthetic and a curette. If the ulcer is larger or more contaminated, debridement should be carried out promptly in the OR, with deep cultures taken to guide antibiotic therapy if infection is also present.¹² After debridement, compression therapy should be initiated. These ulcers often exhibit copious amounts of fluid and exudate; dressings should be chosen according to the amount of exudate present [see Figure 7]. Foam and alginate dressings are often required. Because of the high propensity of these wounds for accumulation of bacteria and biofilm, silver ion-impregnated dressings are also frequently employed.

Although most venous stasis ulcers eventually heal without surgical intervention, certain indications for operative management do exist. Because a venous stasis ulcer is the most extreme manifestation of the underlying disease (i.e., venous insufficiency), it is best treated by first addressing that disease, whether medically or surgically. Many nonambulatory patients may benefit from anti-DVT therapy. Surgery of the superficial venous system is general-

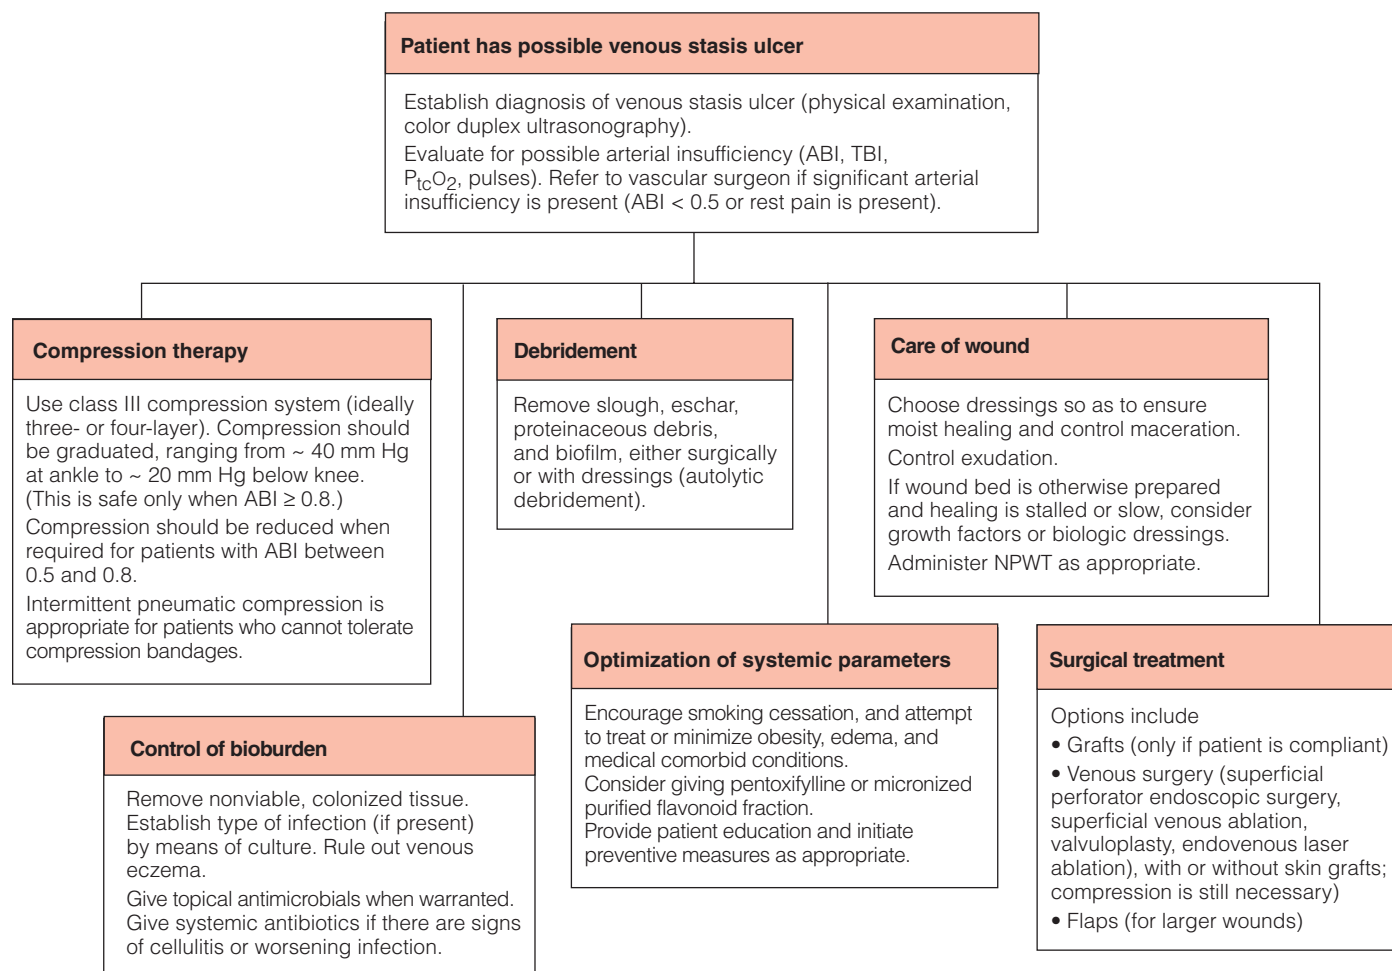

Figure 10 Algorithm illustrates management of venous stasis ulcers.

ly restricted to those patients in whom superficial venous disease is predominant, who show no deep system involvement (i.e., no deep system reflux on duplex imaging), and who are able to ambulate postoperatively (so as to activate the calf muscle pump).^{114,115} In properly selected patients who meet these criteria, surgical management yields faster healing and lower recurrence rates than compression alone does. Certain patients with limited involvement of the deep system may also be candidates for superficial venous surgery, but they will benefit only if vigorous compression is also employed.

Surgical closure is beneficial if the wound is large or causes the patient significant pain. However, it should be undertaken only in compliant patients whose wounds and swelling have been controlled preoperatively with excellent wound care and compression therapy. For these patients, skin grafts can substantially enhance the quality of life. Free flaps are used only to a limited extent in this setting, but there are occasional patients who may benefit from them, including patients with large, deep wounds. Sometimes, flaps can restore a degree of venous drainage to a leg if the anastomosis is performed in the deep venous system or proximally. Some patients benefit from the use of biologic dressings (e.g., Apligraf), particularly when a wound shows signs of stalling after adequate ulcer care.⁶¹ Unfortunately, the recurrence rate after closure of a venous ulcer is high, whether closure is accomplished surgically or not.¹⁰⁴ Patients should be placed on lifelong compression therapy and skin care regimens. Venous stasis disease is controllable but rarely curable.

INFLAMMATORY-VASCULITIC AND OTHER ULCERS

Of the multitude of lower-extremity ulcer subtypes that exist [see *Table 1*], inflammatory ulcers deserve special mention. These lesions, caused by an aberrant inflammatory cascade, are painful, granulated ulcers that resist conventional therapies. As noted (see above), any ulcer that appears not to be healing with proper wound care should undergo biopsy. Proper execution of the biopsy is of critical importance in this setting. Whenever an ulcer is being subjected to biopsy to exclude malignancies or inflammatory processes, specimens should be obtained in several discrete areas. A specimen from the center of the ulcer may not be diagnostic, particularly if necrosis is present. With an inflammatory ulcer, the leading edge of the wound is the area that is likely to have the best diagnostic yield.¹¹⁶ Regardless of the biopsy findings, a careful medical history will generally alert the surgeon to the possibility of an inflammatory ulcer. On examination, such an ulcer shows a characteristic livedo reticularis appearance on the adjacent skin, and the edges often have a dusky hue. The appearance of an ulcer outside the stereotypical distribution pattern may also alert the clinician to an ulcer of unusual origin.

Treatment of a vasculitic ulcer is conducted according to the principles described earlier (see above). Moist healing should be

ensured, and measures should be taken to prevent infection and biofilm accumulation. Debridement usually is not necessary (except for autolytic, nonsurgical debridement), but pain relief and proper dressing selection are. The use of immune modulators (e.g., anti-tumor necrosis factor- α medications) can greatly assist in healing; the use of topical immunosuppressants (e.g., tacrolimus) shows some promise in the care of these ulcers.^{15,116-118} Attempting to close these wounds surgically usually results in failure of the graft or flap unless the inflammatory derangements are first controlled.

Radiation causes not only acute wounds (e.g., radiation dermatitis with acute tissue breakdown) but also delayed wounds, often decades after the initial exposure.¹¹⁹ It must be kept in mind that the effects of radiation on cells and tissues is chronic and ongoing. Local tissue fibrosis and cellular senescence may be present yet may become apparent only when an injury is incurred. Biopsy should be performed to exclude malignancy (in particular, local recurrence of a previously treated neoplasm). Once malignancy is excluded, conservative wound care may suffice for slow healing of the wound. In my experience, however, adjunctive therapies, ranging from HBO¹²⁰ to surgical flaps (especially microsurgical free tissue transfers), are required for most of these wounds. Living biologic tissue-engineered dressings may be useful for shallow wounds.

Sickle cell ulcers develop in the legs of as many as 75% of patients with sickle cell disease, and their incidence increases with advancing age. These lesions are extremely painful, and thus, care depends to a large extent on achievement of proper analgesia, which directly influences compliance with dressings and wound care. Most sickle cell ulcers heal with proper wound care; skin grafts may also be used to achieve expeditious closure when the wound bed is properly prepared.

Tropical ulcers are now being seen more frequently in industrialized nations.¹²¹ Although still rather rare in the United States, they are quite common in the developing world. Accordingly, any patient with a leg ulcer who is a native of a developing or underdeveloped country, particularly if he or she is young, should be worked up for a possible infectious cause. Treatment generally consists of debridement and antimicrobial therapy. After treatment, skin grafting is sometimes undertaken, particularly if the ulcer is large.

Finally, one must always be mindful of the potential for malignancy in a nonhealing wound.¹²² As Dvorak has observed, a tumor may be thought of as a “wound that does not heal.”¹²³ A healthy index of suspicion and biopsy of wounds that do not heal after an appropriate period of therapy are mandatory for ruling out cancer. Malignancies are particularly likely to develop in chronic, inflamed wounds, especially those that have been neglected. Although the prototypical definition of a Marjolin ulcer is that found in a burn wound, squamous cell carcinomas may develop in any chronically open wound.

28 STRATEGIES OF HEMODIALYSIS ACCESS

Robyn A. Macsata, MD, FACS, and Anton N. Sidawy, MD, MPH, FACS

As the population ages and the incidence of diabetes rises, chronic kidney disease (CKD) and end-stage renal disease (ESRD) are becoming increasingly common diagnoses in the United States. In 2005, data from the United States Renal Data System (USRDS) showed that more than 106,000 new patients began therapy for ESRD, whereas the prevalent dialysis population reached 341,000 and the prevalent transplant population reached 143,693¹ [see Figure 1]. Total Medicare costs for CKD patients neared \$42 billion and for ESRD patients neared \$20 billion; this accounts for 13% and 6%, respectively, of the total Medicare spending in 2005[see Figure 2]. Not surprisingly, most of these costs come between the transition from CKD to ESRD and are related to hemodialysis access.² With these ever-increasing numbers and cost of care of renal disease patients, placement of successful long-term arteriovenous (AV) access has become imperative.

As a response to this need, the National Kidney Foundation Kidney Disease Outcomes Quality Initiative (NKF KDOQI) clinical practice guidelines were published, originally in 1997, in an effort to increase the placement of autogenous AV access and to prolong the use of created access by detection of dysfunction prior to thrombosis.³ These guidelines stress early identification of patients with progressive kidney disease, the identification and protection of potential native access construction sites by members of the health care team and patients, and the development of a multifaceted quality assurance program to detect at-risk vascular access,

track complication rates, and implement procedures that maximize access longevity. The guidelines recommend that autogenous AV accesses should be constructed in at least 50% of all new renal failure patients electing to receive hemodialysis as their initial form of renal replacement therapy and that, ultimately, 40% of prevalent patients should have an autogenous AV access.

In 2003, in an effort to reach the goals set forth by the NKF KDOQI guidelines, the Centers for Medicare and Medicaid Services (CMS), the ESRD Network, the Institute for Healthcare Improvement (IHI), and other key provider representatives formed the Fistula First Breakthrough Initiative (FFBI). The work group identified clinical and organizational changes that could be adapted and applied locally by nephrologists, dialysis personnel, access surgeons, and patients to increase the production and use of autogenous AV access. They also identified national system changes such as reimbursement for preoperative vein mapping and reimbursement of autogenous AV access at a higher rate than prosthetic AV access. As a result of the FFBI, the national rate of autogenous access reached 40% prevalence by August 2005; most recent data from December 2009 show a 54.5% prevalence of autogenous access.⁴

In a continuing effort to improve access outcomes, the Society for Vascular Surgery (SVS) recently sponsored a multispecialty expert panel consisting of nephrologists and access surgeons to provide a scientific study of the available evidence

Figure 1 Adjusted incident rates and annual percent changes of US end-stage renal disease (ESRD) patients. Reproduced with permission from United States Renal Data System.¹

in three main areas of AV access: timing of referral to the access surgeon, type of access placed, and effectiveness of access surveillance. Based on this study of the evidence and consensus of the expert panel, the group developed clinical practice guidelines for the surgical placement and maintenance of AV hemodialysis access. These guidelines were published in the *Journal of Vascular Surgery* in November 2008; this chapter is based on that summary document.⁵

Temporary Hemodialysis Access

SHORT-TERM DIALYSIS CATHETERS

Short-term dialysis catheters are double-lumen, noncuffed, nontunneled catheters that can be placed at the bedside without fluoroscopic guidance. These catheters should be placed in patients needing acute dialysis access and should be used for less than 3 weeks' duration. If dialysis is required longer than this time frame, the catheter should be converted to a long-term dialysis catheter. Short-term dialysis catheters may be placed in the internal jugular, subclavian, or femoral veins. With upper extremity catheters, to achieve best flow rates, the distal tip should be placed in the superior vena cava just above the atrial caval junction. The subclavian vein should be avoided if at all possible to prevent central venous stenosis, which may have an impact on future placement of ipsilateral AV access. When femoral access is used, long catheters (24 to 31 cm) should be placed so that the tip can reach the inferior vena cava for the best flow rates.³

LONG-TERM DIALYSIS CATHETERS

Long-term dialysis catheters are double-lumen, cuffed, tunneled catheters that are placed with fluoroscopic guidance

and are intended to be used over weeks to months. As a result of higher blood flow and lower complication rates, access through the right internal jugular vein with the distal catheter tip in the right atrium is preferred^{6,7}; however, left internal jugular and femoral approaches are also suitable. To decrease the risk of central venous stenosis and subsequent venous hypertension, dialysis catheters should be placed contralateral to the side of any maturing or planned permanent AV access and the subclavian vein approach should be avoided if at all possible.^{3,8}

COMPLICATIONS OF TEMPORARY DIALYSIS CATHETERS

The most common indication and main benefit of short- and long-term dialysis catheters is the need for immediate use for dialysis. Other advantages include their universal applicability, their ability to be placed in multiple access sites without hemodynamic compromise, and no need for repeated skin punctures with dialysis sessions. Also, long-term dialysis catheters may be used for months while waiting for permanent AV access to mature. However, less than half of dialysis catheters are removed electively after successful placement of permanent AV access; the remainder are removed as a result of complications. Catheter thrombosis, because of the development of an intraluminal fibrin sheath, leads to removal in up to 31% of patients. Catheter infections are another frequent cause for removal, occurring in up to 20% of patients; this is most commonly seen with short-term dialysis catheters placed in the femoral position.⁹ Catheter malfunction, including cracked catheters, is cause for removal in 1% of patients.¹⁰ Other disadvantages include the discomfort of an external device and lower blood flow rates, leading to longer dialysis times or less effective dialysis.³ A frequently seen long-term complication of dialysis catheters is subclavian stenosis, which occurs in up to 50% of patients with a subclavian catheter in place for as few as 6 weeks and leads to difficulty with permanent AV access.^{8,11,12}

Catheter thrombosis is seen in up to 31% of patients being dialyzed through a long-term dialysis catheter.¹⁰ This is attributable to the development of an intraluminal fibrin sheath with subsequent thrombus formation leading to decreased catheter blood flows and eventually thrombosis. Treatment options include urokinase infusion or fibrin sheath stripping. Both treatment options were shown to have excellent initial success (97% urokinase, 89% stripping) by Gray and colleagues; however, primary patency at 45 days showed a significant reduction (48% urokinase, 35% stripping).¹³ This study demonstrates the continuing need for new catheter placements in patients who do not receive permanent AV access.

Infection rates are higher with short-term catheters (15.6 to 18.9 per 1,000 catheters) compared with long-term catheters (2.9 to 13.6 per 1,000 catheters). Infection rates as high as 20.0 per 1,000 catheters are seen with femoral placement of short-term catheters.^{9,14,15} Sepsis is associated with catheter infection in 0.3 to 1.3 per 1,000 catheters.^{14,16} Organisms most commonly associated with infection include *Staphylococcus aureus*, coagulase-negative *Staphylococcus*, *Enterococcus*, and *Pseudomonas*; often these infections are polymicrobial.^{9,10} Definitive treatment requires removal of the catheter and broad-spectrum intravenous antibiotics. However, catheter salvage may be attempted with broad-spectrum intravenous

antibiotics alone or in combination with guide-wire exchange of the catheter in nonseptic patients.⁹

Permanent Hemodialysis Accesses

TIMING OF REFERRAL

The NKF KDOQI and the SVS clinical practice guidelines both recommend that patients should be referred to a vascular access surgeon for permanent dialysis access when their creatinine clearance is less than 25 mL/min.^{3,5} Once preoperative evaluation is completed, if the patient is felt to be an adequate candidate for autogenous AV access, the access should be constructed as soon as possible to give adequate time to mature; ideally, this should be greater than 6 months before the anticipated need for dialysis. However, given that prosthetic access patency is limited by the time of access placement and not by access use, if a patient is felt to require a prosthetic access, the access placement should be delayed until 3 to 6 weeks prior to the initiation of dialysis.^{3,5}

PREOPERATIVE EVALUATION

History and Physical Examination

A thorough patient history should be taken documenting the patient's dominant extremity, recent history of peripheral intravenous lines, site of indwelling or previous central lines including pacemakers and defibrillators, all previous access procedures, any history of trauma or previous nonaccess surgery to the extremity, and all comorbid conditions, such as diabetes and peripheral arterial disease. On physical examination, the brachial, radial, and ulnar arteries should be evaluated for compressibility and equality bilaterally. An Allen test should be performed to evaluate palmar arch patency. The superficial venous system should be evaluated with and without a pressure tourniquet in place, examining for distensibility and interruptions. The arm should be examined for prominent venous collaterals and edema, which are signs of central venous stenosis. Lastly, a thorough neurologic examination, including sensory and motor functions of the hands, should be performed.³

Arterial Assessment

If any abnormality is noted on the clinical arterial examination, the patient should be further evaluated with segmental pressures and duplex ultrasonography and/or pulse volume recordings. For optimal outcome, there should be no pressure gradient noted between the bilateral upper extremities, the arterial diameter should be equal to or greater than 2.0 mm throughout the extremity, and a patent palmar arch should be present.¹⁷ Any abnormality noted on noninvasive testing should prompt alternate site selection or be further evaluated with an arteriogram, which gives the surgeon the ability to both identify and possibly treat an arterial inflow stenosis. In patients nearing dialysis, the risk of contrast arteriography should be weighed against the need for access to mature before beginning dialysis. Renal protective agents should be used prearteriography; these include intravenous fluids, N-acetylcysteine, and sodium bicarbonate.^{18,19}

Venous Assessment

If superficial veins cannot be visualized with a pressure tourniquet in place or any abnormality is noted on the

superficial venous examination, the patient should be further evaluated with superficial venous duplex ultrasonography. Using venous duplex imaging, superficial veins should be examined for diameter, distensibility, and continuity. Superficial veins should be of a diameter of 2.5 mm or greater to be used for autogenous AV access.¹⁷ Central venous stenosis should be suspected if there are any prominent venous collaterals or edema, a differential in extremity diameter, any history of previous central venous catheter placement, or multiple previous accesses in the planned extremity to be used for access. If any of these abnormalities are identified, the patient should be examined first with deep venous duplex ultrasonography.³ Venography should be performed in patients with either nondiagnostic or abnormal duplex ultrasound imaging for further evaluation and possible treatment.²⁰ As with arteriography, in predialysis patients, the risk of contrast venography needs to be weighed against the need for access to mature in time for dialysis. Patients should be treated pre-venography with intravenous fluids, N-acetylcysteine, and/or sodium bicarbonate.^{18,19}

ACCESS LOCATION SELECTION

Table 1 lists the various types of autogenous and prosthetic AV access available in the upper and lower extremities and body wall. When planning AV access, a few general principles apply:

1. Given their superior patency rates and lower complication rates, autogenous AV accesses should always be attempted before prosthetic AV accesses.
2. As a result of easier accessibility and lower complication rates, upper extremity access sites are used first, with the nondominant arm given preference over the dominant arm.
3. To preserve proximal sites for future accesses, AV accesses are placed as far distally in the extremity as possible.
4. Autogenous AV access configurations, in order of preference, are direct AV anastomosis, venous transpositions, and venous translocations.
5. Lower extremity and body wall access sites are used only after all upper extremity access sites have been exhausted.

Forearm Accesses

Autogenous forearm accesses *Cephalic vein* For autogenous forearm access, use of the cephalic vein is preferred to the basilic vein because of its lateral location and the need for only minimal dissection. Possible sites of arterial inflow include the posterior branch of the radial artery, the trunk of the radial artery, the ulnar artery, and the brachial artery. The ulnar artery is usually not the first arterial option because of its distance from the cephalic vein. The access is placed as distally in the arm as possible where an adequate artery is identified by preoperative evaluation to preserve more proximal sites of inflow for future accesses. Therefore, in patients with an adequate posterior branch of the radial artery, an autogenous posterior radial branch-cephalic wrist direct access (snuff-box fistula) [see Figure 3] is performed. In patients with an inadequate posterior branch of the radial artery but an adequate radial artery, an autogenous radial-cephalic wrist direct access (Brescia-Cimino-Appel fistula) [see Figure 4] is performed. In either of these cases, if the

 - a. Autogenous brachial (or proximal radial)-cephalic upper arm direct access
 - b. Autogenous brachial (or proximal radial)-cephalic upper arm transposition
 - c. Autogenous brachial (or proximal radial)-basilic upper arm transposition
 - d. Autogenous brachial (or proximal radial)-brachial (vein) upper arm transposition
 - e. Autogenous brachial (or proximal radial)-axillary (or brachial) upper arm indirect saphenous vein translocation
 - f. Autogenous brachial (or proximal radial)-axillary (or brachial) upper arm indirect femoral vein translocation
2. Prosthetic
 - a. Prosthetic brachial (or proximal radial)-axillary (or brachial) upper arm straight access

Lower extremity

1. Autogenous
 - a. Autogenous femoral-saphenous lower extremity (straight or looped) transposition
 - b. Autogenous tibial (anterior or posterior)-saphenous lower extremity direct access
 - c. Autogenous femoral-femoral (vein) lower extremity (straight or looped) transposition
2. Prosthetic
 - a. Prosthetic femoral-femoral (vein) lower extremity (straight or looped) access

Body wall

1. Prosthetic
 - a. Prosthetic axillary-axillary (vein) chest (straight or looped) access
 - b. Prosthetic axillary-internal jugular chest looped access
 - c. Prosthetic axillary-femoral (vein) body wall access

Adapted from Sidawy AN, Gray R, Besarab A, et al. Recommended standards for reports dealing with arteriovenous hemodialysis accesses. *J Vasc Surg* 2002;35:603–10.

cephalic vein is felt to be too deep, as seen in obese patients, or is not located in close proximity to the radial artery in the wrist, an autogenous radial-cephalic forearm transposition is performed. If the radial artery is inadequate, the ulnar artery

Figure 3 Autogenous posterior radial branch-cephalic wrist direct access (snuff-box fistula).

Figure 4 Autogenous radial-cephalic wrist direct access (Brescia-Cimino-Appel fistula).

may provide an alternative distal inflow site; alternatively, the entire trunk of either the radial or the ulnar artery may provide an arterial source. If the radial and ulnar arteries are inadequate but the brachial or proximal radial arteries are adequate, an autogenous brachial (or proximal radial)-cephalic forearm looped transposition can be performed.

Basilic vein When the cephalic vein is not felt to be adequate for an autogenous AV access, the basilic vein is the preferred alternative. Secondary to its medial location in the forearm, a transposition is always required. Possible sites of arterial inflow include the distal radial artery, the ulnar artery, the proximal radial artery, and the brachial artery. Use of the posterior branch of the radial artery is usually not possible secondary to the distance from the basilic vein. Similar to the cephalic vein, the AV access is placed as distally in the arm as possible where an adequate artery is identified by pre-operative evaluation to preserve more proximal sites of inflow for future accesses. Therefore, when the radial artery is adequate, an autogenous radial-basilic forearm transposition [see Figure 5] is performed. If the radial artery is inadequate but the ulnar artery is adequate, an autogenous ulnar-basilic forearm transposition is performed. If the distal radial and ulnar arteries are inadequate, the proximal radial or brachial artery may be used to perform an autogenous brachial (or proximal radial)-basilic forearm looped transposition.

Alternative vein If no lower arm vein is available, autogenous access may still be performed with the use of

Figure 5 Autogenous radial-basilic forearm transposition.
(a) Forearm basilic vein is mobilized to the antecubital fossa.
(b) Forearm basilic vein is superficially transposed and anastomosed to the radial artery.

translocated lower extremity veins, including the saphenous or femoral (previously named superficial femoral) vein. Sources of arterial inflow include the distal or proximal radial and brachial arteries. Similar to the cephalic and basilic veins, to preserve more proximal arteries for future accesses, the translocated AV access is placed as distally in the arm as possible where an adequate artery is identified by preoperative evaluation. Therefore, when the distal radial artery is adequate, an autogenous radial-antecubital forearm indirect saphenous vein translocation is performed. If the radial artery is inadequate but the brachial or proximal radial artery is adequate, an autogenous brachial (or proximal radial)-antecubital forearm indirect looped saphenous vein translocation is performed. Alternatively, the femoral vein may be used to perform either an autogenous radial-antecubital forearm indirect femoral vein translocation or an autogenous brachial (or proximal radial)-antecubital forearm indirect looped femoral vein translocation.

Prosthetic forearm accesses If no vein is available, a prosthetic AV forearm access is performed. Sources of arterial inflow include the distal or proximal radial and brachial arteries. Similar to autogenous access, to preserve more proximal arteries for future accesses, the prosthetic AV access is placed as distally in the arm as possible where an adequate artery is identified by preoperative evaluation. Therefore, when the distal radial artery is adequate, a prosthetic radial-antecubital forearm straight access [see Figure 6] is performed. If the radial artery is inadequate but the brachial or proximal radial artery is adequate, a prosthetic brachial (or proximal radial)-antecubital forearm looped access [see Figure 7] is performed.

One of the interesting debates in this area is whether, after exhausting the forearm autogenous options, the surgeon should recommend a forearm autogenous translocated or prosthetic access before proceeding to an upper arm access. The SVS clinical practice guidelines recommend that the surgeon discuss these alternatives and their advantages and

Figure 6 Prosthetic radial-antecubital forearm straight access.

Figure 7 Prosthetic brachial (or proximal radial)-antecubital forearm looped access.

disadvantages with the patient for an informed decision.⁵ If a forearm prosthetic access is chosen, the patient should be told that this access is a “bridge” to an upper arm autogenous access; the patient’s nephrologist should be informed to minimize the number of attempts to salvage the access with endovascular means to avoid damaging the venous outflow so it can still be used for an upper arm autogenous access.⁵

Upper Arm Access

Autogenous upper arm accesses *Cephalic vein* When use of the forearm has been exhausted, efforts at access are directed to the upper arm. Similar to the forearm, use of the upper arm cephalic vein is preferred to use of the basilic vein secondary to its lateral location and need for only minimal dissection. For upper arm access, possible sites of arterial

inflow include the proximal radial and brachial arteries; the AV access is placed as distally in the arm as possible where an adequate artery is identified by preoperative evaluation to preserve more proximal arteries for future access. Therefore, in patients with an adequate cephalic vein, an autogenous brachial (or proximal radial)-cephalic upper arm direct access [see Figure 8] is performed. If the cephalic vein is felt to be too deep or is located far from the artery, an autogenous brachial (or proximal radial)-cephalic upper arm transposition is performed.

Basilic vein When the cephalic vein is felt to be inadequate for an autogenous AV access, the upper arm basilic vein is the preferred alternative. Secondary to its medial and deep location, a transposition is always required. Similar to the upper arm cephalic vein, possible sites of arterial inflow include the proximal radial and brachial arteries; the AV access is placed as distally in the arm as possible where an adequate artery is identified by preoperative evaluation to preserve more proximal arteries for future access. Therefore, in patients with an adequate basilic vein, an autogenous brachial (or proximal radial)-basilic upper arm transposition [see Figure 9] is performed.

Figure 8 Autogenous brachial (or proximal radial)-cephalic upper arm direct access.

Figure 9 Autogenous brachial (or proximal radial)-basilic upper arm transposition.

Alternative vein If no superficial upper arm vein is available, autogenous access may still be performed with the use of transposed brachial or translocated lower extremity veins, including the saphenous and femoral veins. Sources of arterial inflow include the proximal radial and brachial arteries; the AV access is placed as distally in the arm as possible where an adequate artery is identified by preoperative evaluation to preserve more proximal arteries for future access. Therefore, alternative options for autogenous access include autogenous brachial (or proximal radial)-brachial (vein) upper arm transposition, autogenous brachial (or proximal radial)-axillary (or brachial) upper arm indirect saphenous vein translocation, and autogenous brachial (or proximal radial)-axillary (or brachial) upper arm indirect femoral vein translocation. Similar to the lower arm, surgeons should discuss the risks and benefits of the use of an alternative vein for autogenous access in the upper arm for an informed decision before turning to prosthetic access.

Prosthetic upper arm accesses If no vein is available, an upper arm prosthetic AV access is performed. Similar to upper arm autogenous AV accesses, possible sites of arterial inflow include the proximal radial and brachial arteries; the AV access is placed as distally in the arm as possible where an adequate artery is identified by preoperative evaluation to preserve more proximal arteries for future access. Therefore, in patients with no adequate vein, a prosthetic brachial (or proximal radial)-axillary (or brachial) upper arm straight access [see Figure 10] is performed.

Figure 10 Prosthetic brachial (or proximal radial)-axillary (or brachial) upper arm straight access.

Lower Extremity Access

When use of the bilateral upper extremities has been exhausted, efforts are directed to the lower extremity; as a result of the high risk of complications associated with both autogenous and prosthetic lower extremity AV access, a fair amount of debate still exists over the ideal access. Autogenous AV access may be constructed using the saphenous or femoral vein as a conduit. Similar to the upper extremity, patency rates are superior to prosthetic access; however, they are associated with an increased incidence of complications, including wound infections from large vein harvest sites, arterial steal, compartment syndrome, and venous hypertension.^{21,22} Prosthetic AV access has a lower incidence of these complications but continues to have inferior patency rates and a high rate of graft infections. Furthermore, when patients reach the need for lower extremity AV access, they are usually quite advanced in their ESRD and have an overall high mortality rate.^{23,24} Therefore, the SVS practice guidelines recommend that the surgeon discuss these alternatives and their advantages and disadvantages with the patient for an informed decision.⁵

Autogenous lower extremity accesses *Saphenous vein* When use of the bilateral upper extremities has been exhausted, autogenous lower extremity AV access may be performed with the saphenous vein; secondary to its medial and deep location, transpositions are always required. The femoral artery (preferably the superficial or profunda) is used for inflow. Therefore, in patients with an adequate saphenous vein and femoral artery, an autogenous femoral-saphenous lower extremity transposition is performed, either in a loop or straight configuration. Alternatively, in patients with a palpable posterior or anterior tibial artery pulse, either tibial artery may be used as inflow to create an autogenous tibial-saphenous lower extremity direct access.

Femoral vein As an alternative to the saphenous vein, the femoral vein may be used for autogenous lower extremity AV access; because of its medial and deep location, transpositions are always required. The femoral artery (preferably the superficial or profunda) remains the source of inflow. Therefore, in patients with an adequate femoral vein and artery, an autogenous femoral-femoral (vein) lower extremity transposition is performed, either in a straight or loop configuration.

Of note, a high incidence of arterial steal has been related to use of the femoral vein for a conduit in lower extremity access; this is likely attributable to its large diameter allowing for a relatively low-resistance AV access. To avoid this complication, patients should be evaluated for lower extremity peripheral vascular disease; similar to the upper extremity, any inflow lesions should be treated with either endovascular or open surgical techniques before AV access placement or an alternative access site should be chosen. Options to reduce the incidence of arterial steal related to a large diameter femoral vein include femoral vein banding, femoral vein tapering, or constructing a composite femoral vein graft with the saphenous vein.^{21,22}

Prosthetic lower extremity accesses If no lower extremity vein is available or the patient is felt to be too high risk for complications, a lower extremity prosthetic access

may be performed. The femoral artery (preferably the superficial or profunda) remains the source of inflow. Therefore, in a patient with no adequate lower extremity vein and an adequate femoral artery, a prosthetic femoral-femoral (vein) lower extremity straight or looped access [see Figure 11] is performed.

Body Wall Access

After use of both upper and lower extremities has been exhausted, body wall access can be used as a last alternative access site. Body wall access usually requires a prosthetic graft. The main source of arterial inflow is the axillary artery. Sources of venous outflow include the axillary, internal jugular, and common femoral veins. Appropriate options include a prosthetic axillary-axillary (vein) chest (straight or looped) access, a prosthetic axillary-internal jugular chest looped access, and a prosthetic axillary-femoral (vein) body wall access [see Figure 12].

SURGICAL TECHNIQUE

Despite the multiple anatomic options for both autogenous and prosthetic AV accesses, the principles of surgical techniques remain similar in all AV access procedures.

Autogenous AV Access

The following techniques are common to all autogenous vein accesses:

1. After identification of the vein, the distal end is transected and flushed with heparinized saline. This allows for evaluation of the caliber and extent of the vein and identification of any side branches.
2. With transposition accesses, the vein is completely dissected and mobilized, ligating all side branches, to its origin.
3. After controlling the artery, an arteriotomy of a maximum length of 4 to 6 mm is made. The length of the arteriotomy is limited to decrease the incidence of arterial steal.
4. The artery is flushed proximally and distally with heparinized saline to avoid thrombosis during the anastomosis.

Figure 11 (a) Prosthetic superficial femoral-femoral (vein) lower extremity straight access. (b) Prosthetic superficial femoral-femoral (vein) lower extremity looped access.

Figure 12 (a) Prosthetic axillary-axillary (vein) chest looped access. (b) Prosthetic axillary-axillary (vein) chest straight access. (c) Prosthetic axillary-femoral (vein) body wall straight access.

5. The AV anastomosis is performed between the side of the artery and the end of the vein; this configuration decreases the subsequent risk of venous hypertension.
6. The AV anastomosis is performed using a 6-0 or 7-0 monofilament nonabsorbable continuous suture to avoid subsequent anastomotic dilatation.
7. With nontransposed access, after completion of the anastomosis, large venous branches can be ligated through stab incisions. This encourages flow in the main venous segment, which may promote earlier maturation.
8. The patient is asked to perform hand exercises 24 to 48 hours postoperatively to increase blood flow through the vein and encourage early maturation of the access.

Prosthetic AV Access

A standard 6 mm expanded polytetrafluoroethylene (ePTFE) is our choice for graft material for prosthetic AV accesses. Variations in the standard ePTFE graft include thin-walled, extended stretch, external rings, various tapered configurations, and heparin coating, which are all meant to ease handling, provide external support, and improve patency rates. To date, there is only minimal evidence that any of these variations improve long-term results; therefore, use of any of these variations remains a matter of surgeon preference.^{25,26}

The following techniques are common to all prosthetic access:

1. The venous outflow is dissected, examined for appropriate quality and caliber, and controlled with vessel loops.
2. The arterial inflow is dissected and controlled with vessel loops.

3. The subcutaneous tunnel for the prosthetic graft is made with a Kelly-Wick tunneler; the tunnel is made as superficial as possible to allow easy detection by dialysis personnel and as long as possible for a large surface area to prevent repetitive trauma to the same area of the graft and subsequent pseudoaneurysm (PSA) formation.
4. If the venous outflow and arterial inflow are located away from each other, a straight prosthetic AV access configuration is performed. If the venous outflow and arterial inflow are located close to each other, a loop prosthetic AV access configuration is performed; this requires a counterincision at the apex of the loop.
5. The length of the arteriotomy and the venotomy does not need to be limited to 4 to 6 mm. The diameter of the graft will limit the incidence of arterial steal.
6. The artery is flushed proximally and distally with heparinized saline to avoid thrombosis during the anastomosis.
7. The anastomoses are performed using a 6-0 or 7-0 monofilament nonabsorbable suture in a continuous manner.
8. Careful attention to sterile technique is paramount to avoid graft infections.

POSTOPERATIVE FOLLOW-UP

From the time of the access placement, autogenous AV access should be mature and ready for cannulation by 12 weeks postoperatively and prosthetic AV access should be mature and ready for cannulation by as early as 2 weeks postoperatively. Determination of maturity may be done by physical examination alone; the access should have a soft pulse that is easily compressible, a continuous low-pitched bruit, and a thrill near the anastomosis and extending along

the outflow vein and should collapse with arm elevation. If the clinical examination remains equivocal after 6 to 8 weeks, the access should be further evaluated with duplex ultrasonography; the outflow vein should have a vein diameter greater than 4 mm and blood flow greater than 500 mL/min. If the access appears to be failing to mature by duplex evaluation, it should be further evaluated with fistulography or venography to identify any underlying problems preventing maturity. Secondary procedures, such as vein patches, interposition vein grafts, vein transposition to proximal arteries, branch ligations, vein superficialization, or endovascular angioplasties, should then be used to salvage the access.⁵

LONG-TERM FOLLOW-UP

After initial maturation, the AV access should be monitored routinely while the patient is on dialysis. The preferred method of monitoring is monthly determinations of access flow by ultrasound dilution, conductance dilution, thermal dilution, or Doppler technique. Access flow less than 600 mL/min or access flow less than 1,000 mL/min that has decreased by 25% over 4 months should be further evaluated with duplex ultrasonography followed by fistulography if further information is needed. Another method of access monitoring that is more useful with prosthetic access is measurement of static venous dialysis pressures; a graft-to-artery ratio of more than 0.75, a graft-to-vein ratio of less than 0.5, or a progressive increase in the venous or arterial segment of more than 0.25 should be further evaluated with duplex ultrasonography followed by fistulography if further information is necessary. Measurements of dynamic venous pressures have been found to be a relatively poor marker of autogenous or prosthetic access function. Other acceptable methods of access surveillance include measurement of prepump arterial dialysis pressure, measurement of access recirculation using urea concentrations or dilution techniques, evaluation of physical findings such as arm edema, altered characteristics of access thrill, and notation of prolonged bleeding after needle removal. Similar to early access failure to mature, after identification, any underlying abnormalities should be treated with secondary procedures to prevent access thrombosis.³

COMPLICATIONS OF AV ACCESS

AV Access Failure

Upper extremity autogenous AV access [see Table 2] has consistently been shown to have excellent primary and secondary patency rates when compared with prosthetic AV access. One-year primary patency rates of autogenous AV access range from 43 to 85%,^{27–34} and 2-year primary patency rates range from 40 to 69%.^{28,32,35,36} In comparison, 1-year primary patency rates of prosthetic AV access range from 40

to 54%,^{27,28,33,34} and 2-year primary patency rates range from 18 to 30%.^{28,35,36} Similarly, secondary patency rates are superior in autogenous access and range from 46 to 90%^{27,28,31–33} at 1 year and from 62 to 75%^{28,35–37} at 2 years compared with prosthetic access, which ranges from 59 to 65%^{27,28,31} at 1 year and from 40 to 60% at 2 years.^{28,35,36} Also of note, to maintain these secondary patency rates, prosthetic AV access requires a higher number of interventions than autogenous AV access. These superior patency rates of autogenous access include basilic vein transpositions, which have demonstrated 1-year primary patency rates from 35 to 76%^{27,30,32,38,39} and secondary patency rates from 47 to 90%.^{27,32,38}

Similar to upper extremity AV access, lower extremity autogenous AV access [see Table 3] has consistently been shown to have superior primary and secondary patency rates to prosthetic AV access. One-year primary patency rates of autogenous access average 73% and 2-year primary patency rates average 86%.^{21,22} In comparison, 1-year primary patency rates of prosthetic access average 54% and 2-year primary patency rates range from 18 to 47%.^{23,24} Similarly, secondary patency rates of autogenous access at 1 year, which average 86%, and at 2 years, which range from 87 to 94%,^{21,22} remain superior to secondary patency rates of prosthetic access at 1 year, which average 64%, and at 2 years, which average 18%.^{23,24} Also, similar to the upper extremity, to maintain these secondary patency rates, prosthetic AV access requires more revisions.^{23,24}

Early AV access thrombosis Early access thrombosis occurs within 30 days of surgery and is attributable to a technical failure. It is most commonly associated with inadequate venous outflow, which may be secondary to inadequate caliber of the outflow vein or central venous stenosis. Other, less common causes include poor arterial inflow and anastomotic stenosis.

Thrombectomies and thrombolysis are rarely successful treatments for autogenous accesses; this situation usually requires complete revision. If early thrombosis is secondary to the small caliber of the outflow vein, the autogenous AV access is redone using a different vein, that is, conversion of an autogenous radial-cephalic direct wrist access to an autogenous radial-basilic forearm transposition or, if no vein is available, a prosthetic AV access. Central venous stenosis is treated with angioplasty and/or stenting or venous bypass, that is, subclavian vein to internal jugular vein bypass [see Venous Hypertension, below], followed by a new AV access. An arterial inflow stenosis is treated with angioplasty and/or stenting or proximal arterial bypass to restore adequate arterial inflow followed by a new AV access; an alternative approach is to move the AV access either proximally or to another extremity where arterial inflow is adequate. Anastomotic stenosis is a primary technical failure and is redone with close attention to surgical technique.

Table 2 Autogenous Arteriovenous Access Patency Rates

Access Location	Primary Patency (%)		Secondary Patency (%)	
	1 yr	2 yr	1 yr	2 yr
Upper extremity	43–85	40–69	46–90	62–75
Basilic vein transposition	35–76	68	47–90	69–75
Lower extremity	73	68	86	87–94

Table 3 Prosthetic Arteriovenous Access Patency Rates

Access Location	Primary Patency (%)		Secondary Patency (%)	
	1 yr	2 yr	1 yr	2 yr
Upper extremity	40–54	18–30	59–65	40–60
Lower extremity	54	18–47	64	18

Prosthetic AV accesses may be successfully salvaged using thrombectomies or thrombolysis; however, as with autogenous access, the surgeon must evaluate the etiology of the acute thrombosis and revise the access appropriately to prevent recurrent thrombosis.⁵

Late AV access thrombosis Late access thrombosis usually occurs 1 to 2 years after access placement and most commonly is attributable to intimal hyperplasia. In an autogenous access, this occurs just distal to the AV anastomosis but may be seen anywhere in the outflow tract; in a prosthetic access, this occurs at the graft-venous anastomosis. Central venous stenosis is a second common cause of late AV access failure and is attributable to intimal hyperplasia of the central venous system, which is commonly associated with central line placements.

Similar to early access thrombosis, thrombectomies and thrombolysis are rarely successful in autogenous accesses; this situation usually requires complete revision. If late thrombosis is attributable to intimal hyperplasia in the outflow vein, the autogenous AV access is redone using a different outflow vein, that is, converting an autogenous radial-cephalic direct wrist access to an autogenous radial-basilic forearm transposition, or using a proximal site of access, that is, converting an autogenous radial-cephalic direct wrist access to an autogenous brachial-cephalic upper arm direct access. Central venous stenosis is treated with angioplasty and/or stent placement or venous bypass, that is, subclavian to internal jugular bypass [see Venous Hypertension, *below*], followed by placement of a new AV access.

Prosthetic AV access may be successfully salvaged using thrombectomies or thrombolysis if treated within 14 days of access thrombosis and therefore is attempted before abandoning the access for a new site. Given that the inciting lesion is most often located in the graft-venous anastomosis, surgical thrombectomy is performed by exposing this anastomosis, followed by a patch angioplasty to alleviate the outflow stenosis and prevent recurrent thrombosis. Alternatively, a bypass may be performed around the distal anastomosis. Thrombolysis and percutaneous mechanical thrombectomy are alternative methods to reopen the access; however, both techniques must be followed by a contrast study and repair of the inciting stenosis with angioplasty and/or stent placement to prevent recurrent thrombosis of the access.⁵

Failing AV access If an AV access is noted to be failing during routine surveillance while on dialysis, it should be further assessed with duplex ultrasonography and/or fistulography and treated appropriately to prevent access thrombosis. As seen in thrombosed accesses, the inciting lesion is usually intimal hyperplasia located in the outflow tract, and treatment options are similar.⁵

Failure of AV access to mature A common tradeoff for the higher long-term patency rates associated with autogenous AV access is failure of maturation of the outflow vein, leading to inadequate venous dilation and either inability to successfully use the AV access for dialysis or early AV access failure. Initial success rates leading to a functional AV access range from 55 to 97%.^{27,28,31,40,41} These poor maturation rates appear to correspond to the increasing use of small and

suboptimal veins in an effort to perform a higher number of autogenous AV accesses. Other technical issues that may lead to failure of maturation include venous side branches, deep location of the outflow tract, poor arterial inflow, and either arterial or venous anastomotic stenosis.⁵

If any access is noted to be failing to mature, it should be further examined with duplex ultrasonography and/or fistulography. If the AV access appears to be failing because of the small caliber of the outflow vein, treatment options include vein patches, interposition vein grafts, and venous transpositions to proximal arteries. If identified, large side branches of the outflow vein should be ligated; if the outflow vein appears too deep, it should be translocated superficially. Endovascular procedures such as arterial or venous angioplasty and/or stent placements are other options for repair.⁵ Using these secondary procedures, McLafferty and colleagues were able to identify treatable problems with 69% of failing autogenous accesses and successfully salvage the access to functional maturation in 83%.⁴⁰ Similarly, Berman and Gentile demonstrated an overall 10% improvement in achieving a successful autogenous AV access using secondary procedures.⁴¹

Arterial Steal

Arterial steal occurs secondary to low access tract resistance, creating a reversal of blood flow in the arterial outflow tract toward the access and away from the hand; it may be associated with arterial stenosis proximal to the AV access. A subtype of arterial steal, ischemic monomelic neuropathy (IMN), occurs secondary to arterial steal leading to ischemia of the nerves only, producing neurologic deficits of the median, radial, and ulnar nerves, but is not sufficient to cause muscle or skin necrosis.

Using Doppler augmentation or pressure studies, reversal of flow in the arterial outflow tract is demonstrated in 73% of autogenous radial-cephalic direct wrist accesses and 91% of autogenous brachial-cephalic direct upper arm accesses; however, patients are only clinically symptomatic in 0.25% to 1.8% of wrist accesses and 4% to 9% of upper arm accesses.⁴² Clinical symptoms vary and range from mild ischemia presenting as coolness and paresthesias, which occur only on dialysis, to severe ischemia presenting as constant rest pain, numbness, paralysis, finger contractures, and gangrene. Patients with IMN present with acute pain, paresthesias, and weakness or paralysis despite a warm hand and palpable radial and ulnar pulses.

Patients with clinically symptomatic arterial steal should be evaluated with an arteriogram to identify any proximal arterial stenosis; treatment of the proximal artery alone with either endovascular or open surgical techniques may resolve symptoms without the need for ligation or revision of the AV access. In patients without proximal arterial stenosis or who do not resolve their symptoms with treatment of the inflow stenosis, there are multiple options for treatment of the access. Ligation of the access will instantly resolve the symptoms but leaves the patient without a dialysis access. Banding of the access tract [see Figure 13] creates a stenosis that increases the resistance to the blood flow in the access and reverses arterial flow in the distal artery; however, it is difficult to judge the degree of stenosis required to alleviate the steal without causing thrombosis of the access. In patients with a forearm access and a patent palmar arch, the distal

Figure 13 Banding of the outflow access tract. Reproduced with permission from Macsata RA, Sidawy AN. Arteriovenous hemodialysis access. In: Evans SRT, editor. *Surgical pitfalls: prevention and management*. Philadelphia: Elsevier Saunders; 2009. p. 638.

outflow artery may be ligated; however, this approach does not restore possible required inflow to the hand. Distal revascularization with interval ligation [see Figure 14] entails ligation of the arterial outflow tract just distal to the takeoff of the access followed by placement of a bypass from the artery

Figure 14 Distal revascularization with interval ligation.

proximal to the takeoff of the access to the artery distal to the area of ligation. This procedure eliminates reversal of flow in the distal outflow artery while keeping the access patent and perfusion pressures to the hand constant. Complete relief of symptoms has been reported in more than 90% of patients; primary 1-year patency rates range from 86 to 100% for the arterial bypass and from 69 to 86% for the AV access.^{43–45}

High-Output Congestive Heart Failure

High-output congestive heart failure (CHF) is seen only with autogenous AV access. It occurs secondary to decreased total peripheral resistance associated with an AV access that is compensated for by an increase in total cardiac output; the cardiac index should be greater than 2.3 L/min/m². However, in patients with poor cardiac function, as commonly seen in the dialysis population, the cardiac index may still be low as a result of an inability to increase cardiac output to compensate for the AV access flow.

Clinical symptoms are similar to those for low-output CHF and include dyspnea on exertion and at rest, orthopnea, peripheral edema, pulmonary edema, and tachycardia. The diagnosis is difficult; physical examination may be helpful by noting a decrease in the pulse rate with compression of the AV access, the Nicoladoni-Branham sign. Techniques to measure AV access flow rates include the indicator dilution and serial ultrasound dilution measurements; AV access flow greater than 3 L/min or an AV access flow that is greater than 30% of the cardiac output is consistent with the diagnosis.⁴²

Treatment options are limited; ligation of the AV access will resolve symptoms but leaves the patient without dialysis access. Banding of the AV access tract is an alternative approach; however, similar to arterial steal, it is difficult to judge the amount of stenosis required to reduce the cardiac output without thrombosis of the access.

Venous Hypertension

Venous hypertension is seen in both autogenous and prosthetic AV access; it occurs secondary to venous outflow stenosis with or without venous valvular incompetence. The outflow obstruction is commonly located in the subclavian vein as a result of intimal hyperplasia associated with central venous catheters but may also be located anywhere in the venous outflow tract.

Clinical presentation ranges from asymptomatic, with only increased dialysis venous pressures, to symptomatic, including prolonged puncture-site bleeding, extremity edema [see Figure 15a], varicosities [Figure 15b], pigmentation, dermatosclerosis, and venous ulceration.

Patients with clinically symptomatic venous hypertension should be evaluated with duplex ultrasonography and/or fistulography. Central venous stenosis is preferably treated with angioplasty; because of the minimal evidence that stenting increases long-term patency, stents are reserved for unsuccessful angioplasties, occlusions, or recurrent lesions. Open surgical repair is a major undertaking and therefore reserved for percutaneous failures; options include subclavian to internal jugular bypass [see Figure 16] or subclavian vein turn-down. Similar to central venous stenosis, peripheral venous stenosis is preferably treated with endovascular techniques such as angioplasty with or without stenting; open surgery is reserved for percutaneous failures, and options include venous

Figure 15 (a) Upper extremity edema associated with venous hypertension. (b) Upper extremity varicosities associated with venous hypertension. Reproduced with permission from Macsata RA, Sidawy AN. Arteriovenous hemodialysis access. In: Evans SRT, editor. *Surgical pitfalls: prevention and management*. Philadelphia: Elsevier Saunders; 2009. p. 634.

patches, interposition vein grafts, or venous transpositions onto more proximal arteries. Valvular incompetence is treated with ligation of all veins distal to the outflow anastomosis noted to have reflux. If the central or peripheral venous stenosis is not amenable to treatment, patients require ligation of their AV access, leaving them with no dialysis access.^{46,47}

Infection

Infections are more commonly seen in prosthetic (4 to 20% per year) than autogenous (0.56 to 5% per year) AV accesses.

Figure 16 Internal jugular to subclavian venous bypass. Reproduced with permission from Macsata RA, Sidawy AN. Arteriovenous hemodialysis access. In: Evans SRT, editor. *Surgical pitfalls: prevention and management*. Philadelphia: Elsevier Saunders; 2009. p. 635.

Infectious organisms appear to be independent of type of access; there is usually a predominance of gram-positive organisms, most commonly *S. aureus*; however, up to 25% of infections may involve gram-negative organisms or be polymicrobial.⁴²

Clinical presentation may range from diffuse cellulitis or focal abscess overlying the access; patients may or may not be bacteremic. Diagnosis is usually by clinical examination but may be helped with duplex ultrasonography demonstrating fluid surrounding the AV access.

Autogenous AV access infection usually responds to 2 to 4 weeks of broad-spectrum antibiotics; any associated abscess is drained with preservation of the access. A trial of broad-spectrum antibiotics may be attempted in prosthetic accesses presenting with only a mild cellulitis. However, most prosthetic infections require abscess drainage with removal of the infected portion of the graft; if either anastomosis is involved, the entire graft is removed to prevent anastomotic disruption.

Pseudoaneurysm

PSAs are more commonly seen in prosthetic than in autogenous AV accesses, occurring in 2 to 10% of all prosthetic accesses during the functional life of a graft.⁴² They may be seen anywhere along the length of the prosthetic access [see Figure 17] and occur as a result of continuous puncturing of the AV access in the same location by dialysis personnel. When located at either the arterial or the venous anastomosis, they are attributable to graft infection and are treated as such.

Most puncture-site PSAs may be safely monitored without intervention; dialysis personnel should be instructed to use

Figure 17 Puncture site pseudoaneurysms of an arteriovenous access. Reproduced with permission from Macsata RA, Sidawy AN. Arteriovenous hemodialysis access. In: Evans SRT, editor. *Surgical pitfalls: prevention and management*. Philadelphia: Elsevier Saunders; 2009. p. 640.

alternative sections of the access for cannulation. While monitoring, if a PSA appears to be significantly expanding or becomes ulcerated, intervention is indicated. Traditional open surgical treatment is to excise the involved portion of the AV access and replace it with either a transposed vein or a prosthetic graft; in most cases, dialysis is continued by accessing the uninvolved portion of the access. An alternative approach is endovascular treatment with covered stent grafts; current studies show initial success rates up to 100% and primary patency rates at 6 months that range from 29 to 70%.^{48–50}

Seroma

Seromas affect only prosthetic AV accesses. They usually occur within 1 month of placement and most often surround the arterial anastomosis. The exact etiology is unknown, but seroma is presumed to occur from transudation of serous fluid from porous grafts. Clinically, patients present with a slowly increasing fluid collection, which may be further identified by duplex ultrasonography.⁵¹

Multiple surgical treatments have been reported, including serial aspiration, incision and drainage, cyst removal, and graft replacement. Graft replacement has been shown to be the most successful, with a 92% cure rate.⁵²

Hematoma

Dialysis patients most commonly have hemorrhagic complications attributable to uremia-associated platelet dysfunction, which may present as diffuse intraoperative hemorrhage, postoperative hematoma, prolonged puncture-site bleeding, or needle punctures leading to access-site hematomas.

Platelet dysfunction may be medically managed with desmopressin acetate (DDAVP)^{53–55}; other options include cryoprecipitate⁵⁴ and activated factor VII.⁵⁵ With medical therapy, most hemorrhages will stop, and the resulting hematoma will reabsorb without the need for surgical intervention. Expanding hematomas nonresponsive to medical therapy should be explored with the source of bleeding, usually a puncture site, primarily repaired; rarely does this require access ligation.

29 PERITONEAL DIALYSIS ACCESS

Min C. Yoo, MD, Ramesh Saxena, MD, PhD, and Ingemar J.A. Davidson, MD, PhD, FACS

The population of the United States is experiencing a rapid increase in the prevalence of end-stage renal disease (ESRD) requiring renal replacement therapy (RRT). There were over 548,000 ESRD patients in 2008, consuming 7% of the Medicare budget and \$39.5 billion in total costs. With an annual growth of 6%, the ESRD population is projected to grow to more than 775,000 dialysis patients by 2020.¹ RRT options include hemodialysis (HD), peritoneal dialysis (PD), and renal transplantation. Although renal transplantation remains the RRT of choice, the proportion of ESRD patients receiving a renal transplant has not changed in the past decade. With increasing numbers of ESRD patients requiring dialysis, one would expect a proportionate growth of all dialysis modalities. On the contrary, whereas use of HD has progressively increased, there has been a steady decline in PD use.

When compared with HD, PD is associated with patient survival advantages within the first 2 years of dialysis.²⁻⁹ Unlike the sawtooth pattern of treatment with HD, PD delivers a more steady-state treatment by avoiding fluctuations in plasma volume and solutes and is generally better tolerated by the patients with cardiovascular compromise. PD also provides a flexible schedule, allowing patients to work, travel, and participate in daytime activities. As PD does not involve needle sticks, patient anxiety is mitigated, arteriovenous access sites for future HD are preserved, and the risk of acquiring blood-borne infections such as hepatitis C and HIV is minimized. Additionally, residual renal function is better preserved on PD than on HD⁷⁻¹³ and is beneficial to patients who receive a kidney transplant. There is a significantly lower incidence of delayed graft function and better long-term transplantation outcomes for patients on PD pretransplantation.^{7,14-16} Despite these advantages, the number of patients on PD in the United States remains low^{17,18}: PD is used for 8.8% of the total US dialysis population compared with elsewhere in the world, such as the United Kingdom, New Zealand, and Mexico, where PD is used in up to 80% of ESRD patients.

Overview of Peritoneal Dialysis

PD is achieved by instilling a dialysis solution into the peritoneal cavity via a percutaneous abdominal catheter. The peritoneum acts as a dialyzing membrane, across which water and solutes are exchanged between the capillary blood and the intraperitoneal dialysate.⁷ PD can be done manually (continuous ambulatory peritoneal dialysis [CAPD]) or with automated devices (cyclers). Instillation of dialysate can be either continuous (fluid in the abdominal cavity 24 hours a day, i.e., continuous cycler-assisted peritoneal dialysis

[CCPD]) or intermittent, typically at night, with an empty abdominal cavity during the day (nocturnal intermittent peritoneal dialysis [NIPD]).

Table 1 lists the primary indications for PD as defined by the National Kidney Foundation Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines.¹⁸

There are very few absolute contraindications to PD. Inadequate peritoneal membrane surface area or quality, extensive adhesions, and/or other anatomic abnormalities that preclude filtration are the primary contraindications to PD [see Table 2]. Prior abdominal operations are not necessarily a contraindication for attempting PD placement, although intraperitoneal adhesions may make the technique more prone to failure.

Preoperative Evaluation

Preoperative evaluation begins with a thorough history and physical examination. Adequate vision and manual dexterity are required to perform PD because most PD is performed at home by the patient. Patients with physical or mental handicaps can perform PD if adequate assistance is available. The extent and nature of previous abdominal operations, past episodes of peritonitis, recurrent diverticulitis, or pelvic inflammatory disease are associated with increased risk of failure to place the catheter and should be documented but do not represent absolute contraindications to PD. A history of prior open abdominal operations for noninflammatory conditions does not preclude PD placement.^{19,20} In cases where the surgeon suspects that intra-abdominal adhesions will preclude PD catheter placement, it is prudent to plan for HD access placement in the same operating setting. Although PD is the dialysis mode of first choice, the patient should be offered a native vein arteriovenous fistula (AVF) at the same operation, assuming suitable vascular anatomy. This AVF will then have time to mature and serve as a backup for dialysis should PD be temporarily stopped or fail.

Ideally, the PD catheter should be placed 3 to 4 weeks prior to the anticipated initiation of dialysis to avoid complications related to temporary HD catheters. Ideal candidates for PD include working professionals as PD can be performed with less lifestyle disruption compared with in-center HD.

Operative Planning

LOCATION OF THE CATHETER AND MARKING OF THE SKIN

Preoperative planning is essential as 21% of technique failures within the first year are due to catheter-related mechanical problems.²¹ Noninfectious PD catheter-related complications are strongly associated with catheter failure.^{19,22} Ideally, the curled portion of the PD catheter is located in the true pelvis, allowing for proper dialysate instillation and removal or exchanges. The exit site must be easily accessible,

Financial disclosure information is located at the end of this chapter before the references.

Table 1 Indications for Peritoneal Dialysis

Patient prefers peritoneal dialysis
Patient will not do hemodialysis
Patient cannot tolerate hemodialysis
Patient prefers home dialysis but has no assistance for hemodialysis

visible for the patient, and away from the beltline, skin folds, and scars. The subcutaneous tunnel should be fashioned to avoid catheter stresses and kinks. Preoperative planning should also take into consideration the location of the superior border of the pubic symphysis, the umbilicus, the level of the anterior superior iliac spines, and skin folds.²⁰ To decrease the risk of contamination, an alternate presternal extension exit site is preferred in individuals with colostomy or urinary stoma, those who are morbidly obese, and those who desire to take tub baths.²³

With the patient in the upright and supine positions, the incision, intended subcutaneous tract, and exit site of the catheter are marked [see Figure 1]. This is especially important in obese patients as a pannus will change position on standing. In a virgin abdomen, the left side is chosen because the right iliac fossa is the preferred site for a first kidney transplant [see Figure 1]. Also, as opposed to the right side, the downward intestinal peristalsis of the left colon is thought to maintain proper catheter orientation in the pelvis.

As noted in Table 2, obesity is considered a relative contraindication to PD. This is an important consideration because an estimated 70% of the US population is overweight. In recent years, we have been placing an increasing number of catheters in overweight individuals. PD catheters in obese patients work surprisingly well but require special considerations. As noted above, choosing the exit site in the upper abdomen or on the upper chest using a presternal

Figure 1 Skin markings for the placement of a peritoneal dialysis catheter in the open technique. Note the locations of the planned incision, subcutaneous tunnel, and exit site.

Table 2 Contraindications for Peritoneal Dialysis

Absolute
Documented loss of peritoneal function or extensive abdominal adhesions that limit dialysate volume or flow
In the absence of a suitable assistant, the patient is physically or mentally unable to perform PD
Uncorrectable mechanical defects that prevent effective PD or increase the risk of infection (e.g., surgically irreparable hernia, omphalocele, gastroschisis, diaphragmatic hernia, and bladder extrophy)
Relative
Fresh intra-abdominal foreign bodies (e.g., VP shunts or vascular prosthesis)
Peritoneal leaks
Body size limitations
Intolerance to volume exchanges needed for adequate PD dose
Inflammatory or ischemic bowel disease
Frequent episodes of diverticulitis
Abdominal wall or skin infection
Morbid obesity
Severe malnutrition

PD = peritoneal dialysis; VP = ventriculoperitoneal.

extension segment is the preferred option in these patients.^{23,24}

CHOICE OF CATHETER

PD catheters come in a variety of configurations and with one or two Dacron cuffs [see Figure 2]. With single-cuff configurations, the Dacron cuff is placed at the posterior rectus fascia; with double-cuff configurations, the second or outer cuff is placed in the subcutaneous space 1.5 to 2.0 cm from the skin exit site. Although this is not borne out in randomized, controlled trials,²⁵ the double-cuff configuration is thought to provide an additional barrier from bacterial migration along the catheter and may have lower rates of tunnel tract infections and associated peritonitis. Retrospective reviews suggest that double-cuff configurations have a longer catheter survival time, a delayed first episode of peritonitis,^{24,26} and a trend toward decreased episodes of peritonitis.²⁷

The intraperitoneal and extraperitoneal PD catheter designs vary greatly [see Figure 2]. The intraperitoneal

(h) The “self-locating” Di Paolo peritoneal dialysis catheter. Note the weighted tip at the end of the intraperitoneal segment.

segments can be straight, coiled, or weighted (so-called self-locating tips²⁸). Catheters with a coiled intraperitoneal segment provide greater surface area and more side holes for fluid passage and therefore increased likelihood of success.²⁶ The coiled segments may be better tolerated than the straight intraperitoneal configurations because the straight tips are thought to produce more pain with instillation of fluid secondary to a “jet” effect.²³

The extraperitoneal segments can be straight or curved. Because the catheter material has inherent “shape memory,” forcing a curve into a straight catheter is thought to increase mechanical complications and infectious complications and cuff extrusion through the skin.²⁶ We use the double-cuff

curled (pigtail) Tenckhoff catheter with straight external configuration.

Surgical Technique/Approach

The choice of surgical approach depends on the experience of the operating surgeon. PD catheters are typically inserted using an open approach or laparoscopic technique. Other methods of placement include the blind Seldinger technique, placement under fluoroscopic guidance, and placement under peritoneoscopic visualization²⁹; these methods are strongly discouraged because of the risk of inadvertent bowel injury. The open and laparoscopic techniques of PD catheter placement are discussed here.

Advantages and disadvantages exist for both methods. The open approach is associated with a shorter operating time and can be performed under spinal or local anesthesia, although general anesthesia is preferred. The open approach is also more cost-effective as only basic equipment is required for the procedure.³⁰ Laparoscopic placement, with the insufflation of carbon dioxide into the peritoneal cavity, requires general anesthesia, which may be precluded in some patients. Laparoscopic placement also requires longer operating times, a finding that has been consistently reported in multiple studies.^{30–37} The main advantage of the laparoscopic approach is that it allows for direct visualization and placement of the tip of the catheter, as well as the ability to secure the tip of the dialysis catheter in the pelvis.^{35,37} The laparoscopic approach also allows for additional procedures, such as repair of umbilical hernias, lysis of adhesions, or omentopexy.^{38,39}

Laparoscopy is the best technique to rescue problem catheters.^{38,40} Studies comparing the rates of complications with open versus laparoscopic PD placement have been mixed,^{36,37} and one method of placement cannot be recommended over another. The PD catheter surgical approach is greatly influenced by the patient’s medical risk, the operating surgeon’s training, and institutional resources.

OPERATIVE TECHNIQUE

Open Paramedian Approach

Although open PD catheter placement can be performed under local anesthesia, for patient comfort, general anesthesia is preferred. Preoperative antibiotics, such as first-generation cephalosporin (e.g., cefazolin), are administered prior to skin incision. Patients with penicillin or cephalosporin allergies should receive either clindamycin or vancomycin as alternatives.

The skin incision is placed 2 to 3 cm on either side of the umbilicus, with the left being the preferred side [see Figure 1]. The abdominal wall anatomy is shown in Figure 3. The anterior rectus muscle fascia is divided longitudinally. Muscle-sparing technique is used to expose the posterior rectus fascia. Using fine scissors, the posterior rectus fascia and peritoneum are opened for a length of 3 mm. Caution is advised to avoid inadvertent small bowel injury during entry.

A 2-0 polypropylene purse-string suture is placed around the fascial-peritoneal defect [see Figure 4]. The suture is placed so that the tie will be located cephalad to the cuff; this

suture will also be used to secure the inner Dacron cuff to the posterior rectus fascia. This purse-string suture allows for a watertight seal around the catheter.

The intra-abdominal catheter placement is facilitated by the use of a stiffening stylet [see Figure 5]. The catheter must

Figure 4 Several bites (6–8) of suture are placed 5 mm from the edge of the small peritoneal opening circumferentially to form a purse-string closure.

Figure 5 Catheter and stylet.

first be flushed with saline for the stylet to slide freely onto the catheter. The tip of the stylet must not pass outside the tip of the catheter, to minimize the risk of visceral injuries during insertion [see Figure 6]. Once inside the abdomen, the stylet is retracted to release the curled end, and the catheter is directed downward along the anterior abdominal wall. Force must not be used. If resistance occurs, redirection of the catheter is attempted until the pelvis is reached. At this point, the stylet is removed with one hand securing the PD catheter at the exit site. Once the catheter is fully inserted, the purse-string suture is tied snugly. The inner Dacron cuff is then secured to the posterior aspect of the posterior rectus fascia with suture [see Figure 7]. A second purse-string suture is not required. Next, the catheter is tunneled through the rectus muscle [see Figure 8] and pulled through the anterior rectus fascia [see Figure 9]. This step secures the cranio-caudad direction of the catheter, making malpositioning unlikely.

The sharp, curved subcutaneous Faller tunneler is used to create a smooth, curved subcutaneous tract as the catheter exits through the skin [see Figure 10 and Figure 11]. The tunneler is the same diameter as the catheter tubing, making the skin exit site snug [see Figure 12]. A snug exit site minimizes irritation from catheter sliding and the risk of infection. The external Dacron cuff is placed 1.5 to 2.0 cm from the exit site.

Figure 6 (a) This is the ideal position of the stylet as it is inserted through the small peritoneal incision, minimizing the risk of injuries to visceral structures. (b) The catheter with the stylet protruding is dangerous and leads to injuries.

Figure 7 This image details the placement of suture to secure the inner Dacron cuff. Care should be taken not to inadvertently penetrate the catheter.

Figure 8 The catheter is tunneled through the rectus muscle and pulled through the anterior rectus fascia.

Figure 9 The inner Dacron cuff rests sutured to the posterior rectus muscle fascia. The catheter is aligned in a craniocaudal direction, keeping the coiled portion of the catheter straight down toward the pelvis.

Figure 10 The inner cuff is aligned in a craniocaudal direction. The subcutaneous sharp (Faller) tunneler has now been attached to the catheter.

The tunneler should exit the skin at a 30 to 45° angle to optimize catheter alignment to the skin and comfort for the patient. We strongly advise against the technique of using a skin incision at the exit site and retrograde insertion of a hemostat to catch the PD catheter and pulling through the skin. This technique induces bleeding, is traumatic to the skin, and is prone to complications (mainly infection). The larger skin exit defects (and bleeding) with this technique may require stitching at the skin exit site, which further increases the infection risks and external Dacron cuff migration. Stitches must not be placed at the exit site; sutures here cause trauma and tension and promote infection at the exit site. The anterior fascia is closed in a running fashion with a 2-0 polypropylene suture. The skin is closed with an inverted 4-0 polydioxane or polygalactin subcuticular

Figure 11 The sharp Faller tunneler has penetrated the skin at the predetermined and marked site. The external cuff ideally will be located 2.0 to 2.5 cm from the skin surface.

Figure 12 This close-up image of the catheter skin exit site shows the importance of using the correctly sized and fitted tunneling device.

suture and covered with half-inch SteriStrips and a sterile dressing.

Laparoscopic Placement

Although laparoscopic placement of the PD catheter can be performed under local anesthesia and sedation, general anesthesia with endotracheal intubation is safer and preferred for patient comfort. Prophylactic antibiotics are given in the operating room before skin incision, as in the open procedure.

For first-time catheters in a patient with no previous abdominal surgeries, a single camera port and the peel-away catheter sheath are needed. Incidental minor surgical procedures such as small umbilical hernia repairs and omentopexy can also be accomplished with a single port. More complicated and extensive repairs will require additional ports.

The site for Veress needle insufflation should be 1 to 2 inches below the costal margin in the midclavicular line on the ipsilateral side as catheter placement [see Figure 13]. Once pneumoperitoneum is established, the Veress needle is exchanged for the camera port. A 5 mm port is placed into the abdomen under direct vision with the camera inside the device. If the patient has had prior abdominal operations or there are concerns for significant adhesions, open Hasson placement in the supraumbilical midline may be used to establish pneumoperitoneum and gain access to the abdominal cavity.

After surveying the abdomen for injury and incidental pathology, the 0° camera is changed to the 30° lens for improved visualization during the PD catheter insertion steps. The desired level of catheter insertion is determined as a location away from the epigastric vessels, or about 3 cm lateral to the midline and 1 to 2 cm above the level of the umbilicus [see Figure 13]. A 5 to 7 mm transverse incision is made at the selected catheter insertion site. A slightly larger skin incision is helpful when pulling the catheter with the external cuff to the skin exit site. An 18-gauge needle is inserted through the incision site directed at 45° caudad. As the needle is advanced along and between the peritoneum

and the posterior rectus fascia for about 3 to 4 cm, local anesthetic (e.g., bupivacaine 0.25%) is injected along the tract and between the peritoneum and the fascia to create a subperitoneal tunnel and to achieve postoperative pain control. The needle is then used to penetrate the peritoneum about 4 to 5 cm below the level of umbilicus and about 3 cm lateral to the midline in a downward direction.

The syringe is removed and a 0.35-inch internal diameter 50 cm guide wire is inserted. With adequate wire length inside the peritoneal cavity, the needle is also removed, leaving only the guide wire in place. The catheter tract is created using only the stiff dilator inserted over the guide wire with the peel-away sheath off. This facilitates the second pass with the complete peel-away set. While keeping the wire in place, the dilator is removed and inserted into the 22 French peel-away sheath.

The complete set (dilator and peel-away sheath) is now reinserted over the guide wire into the abdomen under direct laparoscopic visualization. When the peel-away sheath is visualized in the abdominal cavity, the inner dilator is removed. The PD catheter is prepared on the back table by inserting the stylet into the PD catheter. The double-cuffed 62 cm long PD catheter with stylet is now inserted into the peel-away sheath, and under direct vision, the PD catheter is advanced until the tip of the guide wire is seen exiting the sheath inside the abdomen.

At this point, the guide is retracted as the catheter is advanced, and the catheter will regain its “pigtail” configuration, which is to be located in the deep pelvis. The catheter is advanced until the inner Dacron cuff is seen. The guide is now completely removed, as is the peel-away sheath. The inner Dacron cuff is pulled back to sit at the posterior rectus muscle fascia or in the rectus muscle. The degree of pull-back is determined based on the length needed to place the external cuff at 1.5 to 2.0 cm from the skin exit site. Next, the curved sharp tunneler is attached to the catheter and penetrated first in an upward and then in a downward curvilinear fashion, out through the skin. This subcutaneous tract step is identical to that in the open procedure. The superficial cuff is placed 1.5 to 2.0 cm from the skin.

Before the camera is removed, the proper position of the curled portion of the catheter in the pelvis is confirmed. Should there be some blood in the abdomen, irrigation through the PD catheter under direct camera vision is performed. After the camera is removed, pneumoperitoneum is released prior to removal of the 5 mm cannula. Port sites are closed with one or two inverted sutures.

Closure and Postoperative Care

With either approach, it is recommended that 40 to 60 mL of saline be left in the abdomen. The newly placed catheter is flushed and aspirated gently with saline or, better, allowed to drain by gravity, ruling out catheter obstruction. Three milliliters of heparin (concentration 1,000 U/mL) is injected into the catheter to avoid catheter obstruction from small blood clots or fibrin. The catheter exit site is covered with 2 × 2-inch gauze wrapped around the catheter to keep the site dry. Dressing changes should be performed in sterile fashion until wound healing is complete. If immediate PD use is required, low-volume exchanges can be initiated within 24 to 48 hours, but it is generally recommended that

Figure 13 Port locations and final position of the peritoneal dialysis catheter after laparoscopic placement.

dialysis be delayed for approximately 2 to 4 weeks, depending on urgency and the postoperative course.

Catheter Removal

PD catheters may require removal for various reasons, such as after a successful renal transplantation or after

technical malfunctions. During preparation, the catheter should first be clamped next to the skin with a hemostat while the external catheter with the transfer set is removed. The catheter is exposed through the previous incision used for open placement, dissected circumferentially, and then sharply divided. The catheter is then followed down to the

rectus muscle and its posterior fascia. The deep cuff is exposed by dividing the rectus muscle and fascia, and the peritoneal defect becomes visible. Placing a 2-0 polypropylene suture at the edge of the defect, before the cuff is completely free, will prevent losing the deep defect. The defect is closed after the catheter is pulled out. This suture is also hemostatic as bleeding can occur into the abdomen. The surgeon should be careful not to splash infected peritoneal fluid during removal of the intraperitoneal segment of the catheter. Cultures are sent as indicated. Depending on location, the external cuff is excised from inside and sharply divided distal to the cuff, which frees the external portion of the catheter. The skin exit site may require skin excision or débridement and one inverted suture to close.

Complications

Catheter-related complications (leaks, peritonitis, obstruction, or hernias) may occur in up to 70% of patients over the lifetime of the PD catheter.²³ The following summarizes the most common problems related to PD catheters.

HERNIAS

Hernias are the most common noninfectious complication related to long-term PD use. The incidence is less than 5% in patients who undergo open catheter placement in the paramedian position but as high as 10 to 15% with a midline incision.²² Patients present with a painless bulge; pain suggests an incarcerated or strangulated loop of bowel. A small umbilical or inguinal hernia can be repaired at the time of PD placement. Symptomatic hernias occurring after initiation of PD should also be repaired. PD can often be resumed postoperatively with a temporarily modified fluid exchange regimen, including more frequent exchanges of smaller volumes and bed rest during exchanges.

LEAKAGE

Leaks can occur at any time, at the catheter exit site or through the wound. An early leak represents poor surgical technique, most commonly imprecise closure of rectus fascia. Watertight closures are not associated with leaks and allow for early catheter use. Resting the catheter for a short period of time (2 to 3 weeks) may allow small peritoneal defects to seal. Most PD dialysis centers wait 3 to 4 weeks before starting fluid exchanges, while cuff incorporation takes place.

Large leaks weeks after placement are unlikely to close with conservative management alone. Repair of a large defect may be difficult and tends to lead to other complications, such as infection. Relocating the catheter to a new site may be the most appropriate option. A large leak in the presence of infection requires catheter removal. Older catheters that have been in place for an extended period of time can also present with a large leak due to mechanical failure (i.e., fracture) of the catheter itself. Depending on the distance from the skin exit site catheter, fractures can be repaired with prepackaged patch kits. Clinical judgment will guide the clinicians as to the best action to follow based on the patient's medical risk, time after catheter placement, and other dialysis options available. The center's team experience also needs to be taken into consideration.

MECHANICAL DYSFUNCTION OR MALFUNCTION

The most common cause of catheter malfunction (usually impaired or slow draining) is constipation, leading to external catheter obstruction.²³ A plain radiograph may identify abdominal pathology and indicate malpositioning of the catheter.

Obstruction is often caused by dislodgment from the pelvis and omental wrapping of the catheter. Temporary relief is sometimes obtained through the forceful injection of saline, thereby displacing surrounding omental tissue. Permanent corrective intervention requires a mini-laparotomy or laparoscopy to remove tissue from the catheter, redirect the catheter into the pelvis, and suture the catheter in place.^{33,38,40} Dislocation is usually detected by concomitant obstruction; the catheter can usually be returned to the pelvis, either by a small infraumbilical midline incision or through a laparoscopic procedure. During the initial catheter placement, correct alignment of the catheter in the rectus as it exits the abdomen prevents later dislodgment. Attempts at fluoroscopic repositioning with a guide wire usually have limited success.

INFECTIONS

Infections involving PD catheters can be classified into three categories, depending on the segment of the catheter involved: exit site infections, tunnel infections, and peritonitis. The treatment varies with the location of infection and the etiology.

Exit Site Infections

Exit site infections present with erythema and purulent drainage from the skin exit site and are most often due to skin flora. Untreated, these infections often progress to tunnel infections and, eventually, peritonitis. Simple infections without drainage are treated with antibiotics and improved local hygiene.^{41,42} Exit site infections involving the superficial cuff can be treated with simple drainage of the site and externalization of the superficial cuff. Externalization of the superficial cuff of a double-cuff catheter converts the catheter to a single-cuff catheter. We generally "shave" the infected cuff at the time of externalization to decrease bacterial burden on the catheter. Drainage and cuff externalization cannot be performed with single-cuff catheters.

Tunnel Infections

Tunnel infections typically present in conjunction with exit site infections but can occur alone. Patients may have tenderness or erythema overlying the catheter tract. Tunnel infections are treated in a fashion similar to that of exit site infections.

Peritonitis

Peritonitis represents the most common cause of technical failure in PD and the most common reason for conversion to HD. Gram-positive organisms are the etiology in a majority of all episodes of peritonitis (44%), with coagulase-negative staphylococcus being the most frequent gram-positive organism of all.⁴³ Twenty-five percent of peritonitis episodes are due to gram-negative organisms, whereas 20% of cases are culture negative. Overall, a center's peritonitis rate

should not exceed one episode per 18 months as recommended by the International Society for Peritoneal Dialysis (ISPD).⁴⁴ Higher rates should result in a review of techniques and reeducation of both patients and staff to ensure that breaks in technique are not contributing to high rates of peritonitis. The routes of peritoneal infection include transluminal contamination (35 to 50%), periluminal contamination at the exit site or along the tunnel (15 to 25%), and intra-abdominal sources (20%). Translocation through intact bowel may be the etiology in the setting of colonoscopy, colitis or diarrhea, or even constipation. A perforated viscus can also cause peritonitis and should be strongly considered in the appropriate clinical setting.

The most common presentation of peritonitis in the PD patient is abdominal pain with a cloudy effluent. A clear effluent does not rule out peritonitis, and a cloudy effluent alone does not always indicate that the patient has peritonitis. Cloudy effluents are also associated with malignancies, chemical peritonitis, or a sample from a “dry” abdomen. If peritonitis is suspected, empirical antibiotics should be started after sending a sample of peritoneal fluid. Antibiotic selection should cover both gram-positive and gram-negative organisms; intraperitoneal administration is superior to intravenous dosing.⁴² In diagnosing peritonitis, an effluent with a white blood cell count of more than 100/μL with at least 50% polymorphonuclear cells is highly suggestive. Even if the cell count does not reach 100/μL, as in the instance of a “dry” abdomen, a proportion greater than 50% polymorphonuclear cells is a strong indicator of peritonitis. Once culture results are available, antibiotic therapy should be tailored to treat identified organisms. An episode of uncomplicated peritonitis is not an indication for catheter removal, but refractory peritonitis (failure to improve after 5 days of appropriate antibiotics) and relapsing peritonitis (recurrence after 4 weeks of treatment) often require catheter removal. Coagulase-negative staphylococcal infections can lead to the formation of a biofilm that results in recurrent peritonitis; catheters infected by these organisms should also be removed. Fungal and polymicrobial peritonitis are indications for immediate catheter removal.

Summary

PD remains an underused modality for renal replacement, despite ample evidence of improved survival and quality of life when compared with HD. Careful patient selection and planning by the surgeon as part of a multidisciplinary team caring for the ESRD patient can lead to long-term success with PD. One-year actuarial catheter survival of 80% should be expected by ISPD standards.^{25,35,44} Catheter survival rates as high as 91% at 3 years can be accomplished with proper patient management.¹⁹

30 DESCENDING THORACIC AND THORACOABDOMINAL AORTIC ANEURYSMS: OPEN AND ENDOVASCULAR REPAIR

Nathanial Fernandez, MD, and Robert Y. Rhee, MD

Background

Descending thoracic aneurysms (DTAs) are less prevalent than their abdominal counterparts, with rates reported in the range of 10 cases per 100,000 person-years.¹ Isolated involvement of the descending thoracic aorta occurs in 30 to 40% of all thoracic aneurysm cases.¹⁻³ In one population-based study of thoracic aortic aneurysms, the ascending aorta and aortic arch involvement occurred in 40%, isolated DTA in 31%, and the entire arch and descending thoracic aorta in 29%.¹

Thoracoabdominal aortic aneurysms (TAAAs), like DTAs, are less common than abdominal aortic aneurysms (AAAs).⁴ Similar to AAA disease, there appears to be some degree of genetic predisposition. It has been reported that as many as 20% of patients with TAAA will have a first-degree relative with a thoracic or thoracoabdominal aneurysm.⁵ In addition to the familial link, TAAA has been associated with multiple genetic syndromes. Marfan syndrome (involving a mutation in the fibrillin-1 protein found on chromosome 15) is the most common genetic syndrome associated with TAAAs. These patients tend to develop aneurysms at an earlier age (late third to fourth decade) than other TAAA patients (from atherosclerotic disease) who commonly present with aneurysms when they are older than 60 years. Other genetic syndromes that have been associated with the development of a TAAA are Turner syndrome, Ehlers-Danlos syndrome, and polycystic kidney disease.⁶

TAAAs are also associated with a previous or chronic type B aortic dissection. To that end, as many as 25% of patients with a known TAAA will have had a chronic type B dissection.⁷ Historically, it is estimated that between 20 and 40% of the aortas involved with type B dissections will degenerate into a TAAA over the first 2 to 5 years following diagnosis. A less prevalent percentage of patients with a TAAA will be mycotic (infected) in nature. In mycotic TAAA, cultures will commonly identify *Staphylococcus* species, *Salmonella* species, and *Streptococcus* species, with less commonly identified microbes including *Enterococcus* species, *Escherichia coli*, *Bacteroides* species, and fungal infections.^{8,9}

The main goal of treatment of descending thoracic and thoracoabdominal aneurysms is the prevention of rupture and

death. The natural history of DTAs is poorly defined. In patients with a DTA followed without intervention, it has been estimated that 32 to 43% of these aneurysms will eventually rupture^{5,10} and that more than 90% of these ruptures will be fatal if not treated, whereas survival for patients operated on for rupture has been reported as between 56 and 76% depending on the patient's condition at the time of operation.^{2,11} The reported risk of rupture is varied, but Clouse and colleagues reported the cumulative risk based on size over a 5-year period to be 0% for aneurysms less than 4 cm in diameter, 16% for aneurysms with a diameter between 4 and 5.9 cm, and 31% for an aneurysm larger than 6 cm.¹ In patients with DTA and TAAA, it has been found that hypertension, chronic obstructive pulmonary disease (COPD), and renal failure are risk factors for rupture, with the size of the aneurysm being the most important predictor of rupture.¹² Notably, an aneurysm with a diameter of 6 cm or more has been associated with a fivefold increase in the chance of rupture.¹³ Based on longitudinal data; the thoracic aorta will have an average annual growth rate of approximately 0.1 cm per year. The descending thoracic aorta seems to grow faster than the ascending, 0.19 cm per year versus 0.07cm, and the rate of growth tends to accelerate as the aneurysm gets larger.⁵

For thoracoabdominal aneurysms, like thoracic aneurysms, size is felt to be the single most important risk factor for rupture. Increased rates of growth are also felt to be predictive of an increased chance for rupture. At our institution, growth greater than 1 cm in a year is used as an indication for repair if the patient is a relatively good risk for an intervention. Other factors associated with an increased risk of rupture include advanced age, the presence of coronary artery disease, the presence of COPD, and renal insufficiency.¹¹ Growth rates for TAAA are also variable, with rates ranging between 0.1 and 0.45 cm per year, with faster rates of growth for larger aneurysms. Cambria and colleagues reported an annual growth rate of 0.2 cm per year.¹⁰ In that study, the expansion rate was not influenced by the size at diagnosis, presence of hypertension, tobacco use, or renal failure.¹⁰ They did, however, note an association with increased rates of expansion and COPD, which has also been noted in other studies. Overall rupture rates were 12% at 2 years and 18% for those aneurysms larger than 5 cm.

Survival for patients with DTAs and TAAAs is generally poor compared with that for the general population. The 5-year mortality for DTAs exceeding 6 cm varies from 38 to 64%.¹² One population-based study looking at survival and prognosis for patients with degenerative thoracic aneurysms showed a 5-year survival of only 56%. Rupture was the leading cause of death in this cohort and accounted for 30% of all deaths. Other associated mortality etiologies include cardiac events (25%), pulmonary causes (15%), cancer (10%), and stroke (4%).¹ For thoracoabdominal aneurysms treated nonoperatively, Cambria and colleagues showed an overall survival of 69% at 2 years and 39% at 5 years.¹⁰ A retrospective study looking at the outcomes of 170 aortic aneurysms treated nonoperatively showed 5-year survival of only 39% for thoracic aortic aneurysm (TAA) and 23% for TAAA.¹³ Multivariate analysis revealed that aneurysm diameter, the presence of renal failure, and hypertension were significant risk factors impairing survival. Additionally, the presence of renal failure and aneurysm diameter (greater than 6 cm) were predictive of a fivefold increased risk of rupture.¹³

Evaluation

PRESENTATION

The majority of DTAs are asymptomatic at the time of presentation and are found most commonly as an incidental finding during workup and imaging done for evaluation of another disorder. TAAAs, on the other hand, are asymptomatic at the time of discovery in approximately 43% of patients, 49% will present with symptoms other than rupture, and 9% will present with a leak or frank rupture.¹⁴

The most common presenting complaint for those symptomatic aneurysms that are not ruptured is ill-defined chronic back pain. Often back pain that is musculoskeletal in origin is difficult to differentiate from pain related to the aneurysm. Both types of aneurysms may cause symptoms owing to a local mass and pressure effects as well. These may include hoarseness, which can result from vocal cord paralysis secondary to compression of the left recurrent laryngeal or vagus nerves. This is most commonly seen in patients with large aneurysms of the proximal descending thoracic aorta. Patients also may experience respiratory difficulty or dyspnea related to compression of the tracheobronchial tree. Dysphagia can also occur as a result of extrinsic compression of the esophagus by a large aneurysm. A large TAAA with an extended paravisceral segment can induce pressure against the duodenum and cause weight loss related to early satiety or obstruction or a vague sensation of “fullness,” which may prevent the patient from eating adequately. Rarely, direct erosion of the aneurysm into the adjacent tracheobronchial tree, esophagus, or both can cause exsanguination, presenting as massive hemoptysis or hematemesis, or, less frequently, slow intermittent blood loss [see Table 1].

IMAGING

Given that the majority of patients with DTAs or TAAAs are asymptomatic, most patients are diagnosed incidentally on routine imaging studies done to evaluate another disorder.

For the evaluation of thoracic and thoracoabdominal aortic aneurysms, the primary imaging modality and the most definitive is contrast-enhanced computed tomography (CT) or

Table 1 Symptoms Attributable to Thoracic and Thoracoabdominal Aortic Aneurysms

TAAA = thoracoabdominal aortic aneurysm.

computed tomographic angiography (CTA) of the chest, abdomen, and pelvis. CTA is extremely accurate in its ability to define the aortic anatomy and the extent of the aneurysm. CTA can also precisely define the aortic lumen and outer diameter, (including the distinction between the true and false lumen in acute aortic dissection) and show the presence or absence of mural thrombus and inflammatory changes in the aortic wall. In addition to providing good spatial resolution and accurately evaluating the aorta, it allows you to assess other intrathoracic, intra-abdominal, or intrapelvic solid organs. Evaluation of the aorta for follow-up studies or in patients with renal impairment can be done without contrast if one is interested only in evaluating size progression. CTA is currently the imaging modality of choice for the evaluation of the extent of and the operative planning for DTA and TAAA.

Magnetic resonance angiography (MRA) is another noninvasive imaging modality that is widely available and can be used to evaluate the aorta and its branches. It has the benefit over CTA of not requiring iodinated contrast and can be used in patients with impaired renal function. Previously, gadolinium-enhanced MRA was used over CTA in patients with renal dysfunction, but recognition of the association between nephrogenic systemic fibrosis and the use of gadolinium in this patient population has limited the utility of gadolinium and at least this theoretical benefit of MRA over CTA.¹⁵ Non-contrast-enhanced MRA can still be done with good results, but the spatial resolution on an MRA has been shown to be not as precise as with CTA. Additionally, MRA does not show calcifications or mural thrombus as well as CT.

Transesophageal echocardiography is an invasive imaging modality and is more operator dependent than CTA or MRA. It is a useful tool for evaluation and diagnosis of aortic dissections, especially involving the ascending aorta. It can provide excellent images of the thoracic aorta but does not allow for evaluation of the whole aorta. It can be useful in the operating room too for showing aortic wall disease and assessing cardiac function. Standard duplex scanning (because of the constraints of the chest cavity) cannot image the descending and ascending aorta adequately to be useful as a standard diagnostic tool.

CLASSIFICATION

Aneurysmal disease can involve all segments of the ascending aorta, aortic arch, and the descending thoracic aorta or any combination of these. DTAs are classified as type A if they extend from the left subclavian artery (LSA) to the levels

of the sixth thoracic vertebrae, type B if they extend from T6 to the levels of the diaphragm, and type C if they go from the LSA to the diaphragm [see Figure 1].

A different classification scheme exists for aneurysms involving the thoracic aorta and visceral segment of the abdominal aorta or TAAA. The full extent of the aneurysmal involvement is defined by proper imaging, most commonly CTA. TAAAs are normally classified according to the extent of the aneurysmal involvement of the aorta. Type I classically involves the descending thoracic aorta distal to the LSA and ends above the renal arteries. Like type I, type II involves the thoracic aorta distal to the LSA but extends down to below the renal arteries. Type III extends from the sixth intercostal space or mid-descending thoracic aorta to below the renal arteries. Type IV TAAAs generally involve most if not all of the abdominal aorta, from the 12th intercostal space to the iliac bifurcation [see Figure 2].

PREOPERATIVE EVALUATION

Prior to proceeding with repair of a DTA or a TAAA, patients must be thoroughly evaluated medically to determine if they are physiologically fit enough for repair as this will influence decision making regarding the course of treatment. In addition to a thorough history and physical examination, screening tests to include basic metabolic profile, complete blood cell count, coagulation laboratory tests, chest x-ray, and an electrocardiogram should be obtained.

Generally, patients with thoracic aneurysm disease have multiple comorbidities. Therefore, extensive organ-specific evaluation of the patient's pulmonary status, cardiac status,

and renal function should be obtained prior to treatment. Conditions such as COPD can severely hamper the ability of the patient to recover from a significant, direct operation involving the chest cavity. COPD is defined by a clinically documented history of COPD or pulmonary function tests showing a forced expiratory volume in 1 second (FEV₁) of less than 70% of predicted. The incidence of COPD has been reported in 30 to 40% of patients with TAAA and is associated with increased risk for operative morbidity and mortality, particularly with open repair.^{16,17} It is important to get an accurate and thorough workup of the patient's pulmonary status if he or she is being considered for open repair of a DTA or TAAA. All candidates for open repair should therefore undergo complete pulmonary function testing. Every attempt should be made to improve lung function preoperatively, if possible. This may include immediate cessation of tobacco smoking, initiation of chest physical therapy, administration of bronchodilators, and antibiotics when indicated. Patients with severe pulmonary disease and prohibitive risk for open repair of TAAA should be considered for other, less invasive modes of treatment, such as hybrid endovascular repair.¹⁸

Coronary artery disease, like COPD, is also common in this patient population. All patients undergoing evaluation for repair of a thoracic or thoracoabdominal aortic aneurysm require a thorough cardiac evaluation. This includes a stress test with evaluation of left ventricular function. In the majority of patients, this involves a chemical stress test, which can define ventricular function and screen for reversible cardiac ischemia. Patients with a positive stress test should undergo cardiac catheterization and any indicated coronary artery revascularization

Figure 1 Classification of descending thoracic aortic aneurysms: (a) type A, left subclavian artery to T6; (b) type B, T6 to the diaphragm; or (c) type C, left subclavian artery to the diaphragm. Adapted from Estrera AL et al.¹⁶

Figure 2 Crawford classification: type I extends from the proximal descending thoracic aorta to the upper abdominal aorta; type II from the proximal descending thoracic aorta to below the renal arteries; and type III from the distal half of the descending thoracic aorta to below the renal arteries; type IV involves most of or the entire abdominal aorta.

prior to open repair of a DTA or a TAAA. In patients who undergo percutaneous coronary artery angioplasty and stenting and who require clopidogrel, repair should be delayed long enough so that the clopidogrel can be stopped safely without increased risk of stent thrombosis. The clopidogrel is generally held for 7 days prior to open repair of a DTA or TAAA. In patients who are candidates for thoracic endovascular aortic repair (TEVAR), the clopidogrel does not need to be discontinued. In patients who undergo coronary artery bypass before repair, saphenous vein grafts are preferable to using the left internal mammary. This reduces the risk for cardiac ischemia if cross-clamping proximal to the LSA is required during open repair or if coverage of the LSA is necessary during TEVAR. Additionally, the internal mammary artery may provide important collateral blood supply to the spinal cord.

Finally, preoperative evaluation of a patient's renal function is mandatory as preoperative renal insufficiency (creatinine greater than 2.0 mg/dL) is a known significant risk factor for poor outcome and mortality.¹⁴ Preoperatively, nephrotoxic medications should be held and exposure to iodinated contrast should be minimized as much as possible. Renal function should be optimized with brisk preoperative hydration when necessary.

Management

THORACIC ANEURYSMS

Indications for Repair

The evaluation and decision-making process for the treatment of DTA are based on prevention of rupture and

minimizing the morbidity and mortality associated with repair. Any symptomatic or ruptured aneurysm mandates urgent repair regardless of the patient's risk factors. Obviously, given that the risk of operative intervention is relatively high, the patient and the family must be made fully aware of all of the possible associated morbidities and consequences of an unsuccessful repair attempt. For asymptomatic patients with nonruptured aneurysms, the decision-making process is a little more complex. Given that the size of the DTA is the number one predictor of the risk of rupture, findings on imaging revealing the diameter to be 6 cm or greater are generally considered an indication for repair at our institution provided that the patient is able to medically tolerate such an operation. Additionally, evidence that the aneurysm has grown at a rate of greater than 1 cm per year is a relative indication for repair. In patients with DTA of less than 6 cm, observation for a period of 6 months with rigorous follow-up imaging is indicated. Follow-up imaging may be performed with repeat CTA or noncontrast CT for a patient with renal insufficiency. If, at any point, the size increases to greater than 6 cm, there is evidence of rapid growth (> 1 cm/year), or the patient has developed any symptoms directly attributable to the aneurysm, we would initiate the process for workup for possible repair [see Figure 3]. Clearly, patients should be instructed that if at any point during the observation period they develop new symptoms attributable to the aneurysm, they should seek medical treatment immediately. If the aneurysm is stable on two consecutive studies, then the aneurysm surveillance can be extended to every 12 months.

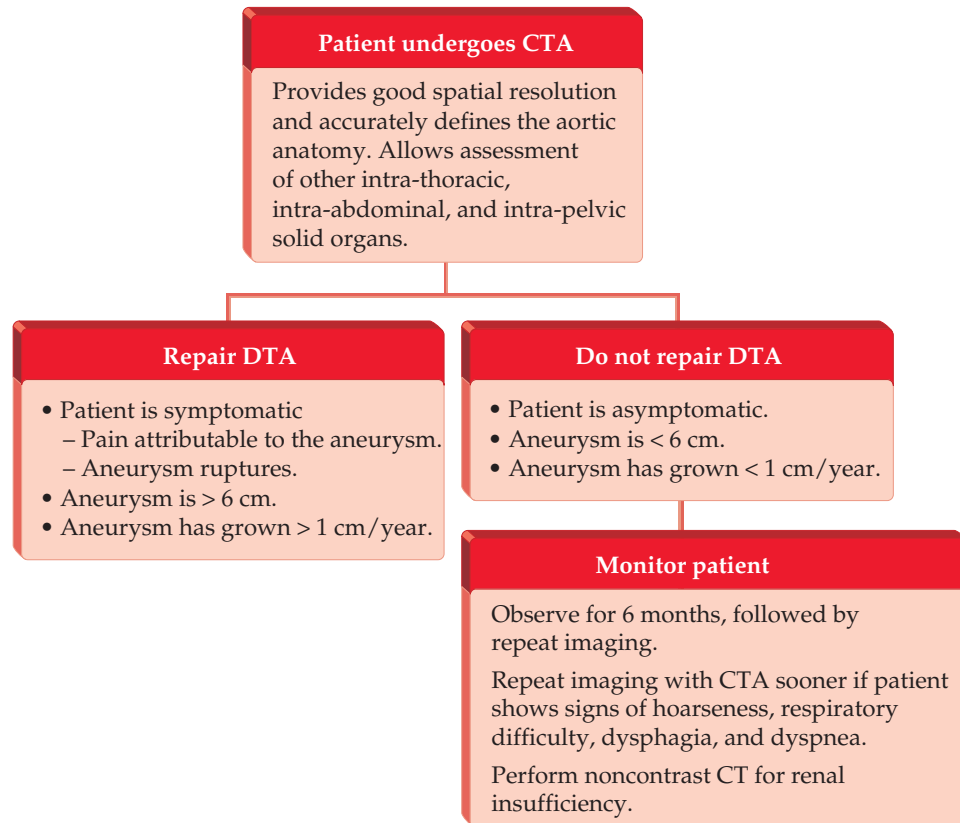

Figure 3 Evaluation of a patient with a thoracic aortic aneurysm. CT = computed tomography; CTA = computed tomographic angiography; DTA = descending thoracic aortic aneurysm.

Repair of DTAs

Open repair of DTA has traditionally been a procedure associated with high morbidity and mortality and has been offered primarily to good surgical candidates. Perioperative death rates exceeding 10%, a paraplegia risk of 4 to 5%, and the physiologic stress of recovery from a thoracotomy make this a difficult option for most patients.^{19,20} Despite advances in surgical technique and perioperative care, open repair of a DTA remains a difficult, often morbid undertaking for patients. Reported complications of open repair include bleeding requiring reoperation (2%), paraplegia (7.5 to 14%), myocardial infarction and all cardiac events (20%), pulmonary insufficiency or pulmonary complications (20 to 50%), and renal failure (13 to 20%).^{21–23}

TEVAR offers the benefits of aneurysm exclusion without the physiologic insult of prolonged proximal aortic cross-clamping and direct surgical exposure, which may improve early morbidity.²¹ This technique was first introduced by Dake and colleagues in 1994 and has become a mainstay of treatment for isolated DTA with favorable anatomy.²⁴ Currently, three endografts are approved by the Food and Drug Administration (FDA) for use in treatment of thoracic aortic pathology and are intended for the endovascular repair of fusiform and saccular aneurysms as well as penetrating ulcers of the descending thoracic aorta in patients with appropriate anatomy. The GORE Excluder (TAG) device was the first thoracic endograft to gain FDA approval. It is designed to

treat aortic neck diameters no smaller than 23 mm and no larger than 37 mm. The Medtronic Talent Thoracic stent graft gained FDA approval in 2008 and is intended to treat aortas with a nonaneurysmal aortic diameter in the range of 18 to 42 mm. It is made of inlaid stents and polyester fabric, and the largest size available is 46 mm. The Cook Zenith TX2 is the third approved endograft and is approved to treat aortas with a proximal neck and distal landing zone with diameters from 24 to 38 mm. It is a two-piece device with both proximal fixation hooks and distal fixation spines [see Figure 4].

There are, however, significant anatomic restrictions for TEVAR. To maximize fixation and obtain an adequate seal, the proximal and distal segments of the aorta must be relatively disease free, small enough in size, and an adequate length (greater than 2 cm) for the currently available endografts [see Figure 5]. To increase the indication for proximal aortic treatment, one may need to cover the origin of the LSA, which is generally well tolerated. In one retrospective review of 171 patients who underwent thoracic endograft for repair of DTA, 22 (12.9%) patients had a distance from the LSA to the beginning of aneurysm, or the primary entry site of a dissection was < 1.5 cm and required coverage of the origin of LSA. None had acute symptoms of malperfusion, and at the 2-year follow-up, 68% were asymptomatic, with 32% having mild symptoms and none requiring revascularization.²⁵ One exception is in a patient with previous coronary artery bypass in which the

Figure 4 Available thoracic endografts. (a) Gore-Excluder (TAG); (b) Medtronic Talent; and (c) Cook TX2.

left internal mammary artery has been used as a graft to revascularize the heart. In this setting, it is recommended that an LSA transposition or carotid subclavian bypass be performed prior to covering the LSA. Another indication for revascularization of the LSA would be the development of significant upper extremity ischemic symptoms.

Outcomes of Repair for DTA

The theoretical benefit of endovascular repair over open repair is based on the concept that TEVAR is associated with less morbidity and mortality. Even at centers of excellence, morbidity from elective open surgical repair is significant with paraplegia rates of 5 to 21% and 30-day mortality between 5 and 20%.²⁶

The risk of paraplegia with TEVAR for DTAs appears to be less than with open repair, with various studies reporting perioperative paraplegia rates of 0 to 4%.^{26–30} Factors thought to be associated with an increased risk for paraplegia in TEVAR include coverage of the LSA, extensive coverage of the distal thoracic aorta, previous AAA repair, and compromised internal iliac artery circulation.^{27,30} When any of these factors are present, the use of spinal drainage is recommended, as well as maintenance of mean arterial pressures > 90 mm Hg during the procedure and early postoperative period.³⁰

TEVAR results have had encouraging short-, intermediate-, and now longer-term survival outcomes. In the perioperative period, multiple studies have shown very low 30-day mortality rates of 1.5 to 6.9%.^{26–30} Additionally, the reported survival rates have been encouraging, with 1-year overall survival rates of 83% and aneurysm-related survival of 86%. At 2 years, the

reported survival rates are 75 to 77%, and the 5-year survival is 64%.^{27,29,30} These results compare favorably with the overall 5-year survival with open repair of approximately 56% in a recent population-based study.¹

A problem unique to endovascular repair is the presence or development of endoleaks. These occur because (unlike in an open repair, where the graft is sewn to the vessel wall) exclusion of the aneurysm relies on radial force and in some cases fixation barbs to obtain a good seal and hold the stent graft in one place, preventing migration. Perioperative endoleak rates have recently been reported to range from 2.2 to 9.4% of patients, with late endoleaks accounting for another 2.2 to 9%.^{21,27–30} These endoleaks most often can be managed with a repeat endovascular intervention. Many are fortunately not clinically significant and can be observed.^{21,27–30}

However, no prospective studies have compared open surgical repair and TEVAR for the treatment of a DTA, but many of the results from TEVAR have been compared with the historical results reported for open repair. One study looking at and comparing the results of the endovascular stent grafting for the treatment of DTA with those of an open surgical cohort control group involved 140 patients treated as part of the Gore TAG trial.²¹ Comparing operative mortality between the two groups revealed a perioperative mortality of 2.1% in the endograft group versus 11.7% with open repair. Similarly, the rates of spinal cord ischemia (SCI) favored the endograft group, with the total incidence of SCI being 2.9% versus 13.8% in the open surgical control group. Kaplan-Meier analysis revealed similar survival, with an estimated 2-year survival of 78% and 76% in the endograft group and

Figure 5 Anatomic restrictions for thoracic endovascular aortic repair (TEVAR).

the open cohort, respectively. Finally, there were no cases of aneurysm rupture in either cohort.

Another study compared the results of endovascular and open repair for the treatment of DTAs and TAAAs. A total of 724 patients underwent repair, 352 in the endograft group and 372 in the surgical group. The patients in the endograft group were, on average, 9 years older and had a higher incidence of coronary artery disease and COPD as well as a lower glomerular filtration rate. Despite the relative increased age and comorbidities, there was a trend toward better survival at 30 days, with a perioperative mortality of 5.7% in the endograft group versus 8.3% in the surgical group. Additionally, there was no difference in survival at 12 months, and there was a borderline difference in the incidence of SCI favoring the endograft group: 4.3% for the endovascular group and 7.5% for the open repair group.²²

Based on these promising results, TEVAR has become the primary mode of treatment of DTAs at our institution and in most hospitals that treat such diseases.

THORACOABDOMINAL AORTIC ANEURYSM

Indications for Repair

The initial evaluation of a patient with a TAAA is similar to that done for a thoracic aortic aneurysm and again centers on the goal of preventing rupture and minimizing the

morbidity and mortality. Evaluation of a patient with a TAAA should include a CT angiogram of the chest abdomen and pelvis to define the anatomy and extent of the aneurysm as well as rule out rupture or signs of impending rupture. Any symptomatic aneurysm or aneurysm with evidence of rupture mandates emergent repair. As with all aneurysms of the aorta, size is the number one predictor of the risk of rupture.

After the initial evaluation and CT angiography are done, the next step in the decision-making process is based on the size of the aneurysm. If the aneurysm is less than 6 cm, then the patient should be observed and seen again in 6 months with a repeat CT scan. If the aneurysm size is stable, without signs of rapid growth (greater than 1 cm per year), and less than 6 cm in diameter, then the plan of observation should be continued. If the TAAA is stable after two consecutive evaluations at 6-month intervals, then this can again be extended to once a year. If there is continued slow growth of the aneurysm, serial evaluation is undertaken every 6 months until the aneurysm reaches the size of 6 cm, at which point, the patient would undergo further evaluation or workup to evaluate fitness for possible repair [see Figure 6].

If the aneurysm is 6 cm in diameter or greater, or if on follow-up it increases in size to 6 cm, then workup of the patient's physiologic status should be done to determine the patient's tolerance for open, direct repair. TAAA repair has significantly higher morbidity and mortality than even open DTA repair. Basic metabolic laboratory tests should be obtained, as well as a chest radiograph, pulmonary function tests (similar requirements for patients with a DTA), and an electrocardiogram. Preoperative renal dysfunction is a significant predictor of postprocedure renal failure. Postoperative renal failure is, in turn, associated with increased mortality.^{14,17} The patient's pulmonary status and cardiac status are the two most important physiologic factors that guide the patient's course of care [see Figure 6].

The options for care of these patients include direct open repair, debranching procedure with subsequent endograft repair, branched or fenestrated endograft repair, or continued observation. Care of the patient should be individualized to the patient based on the anatomy of their aneurysm and overall functional status, especially related to the patient's pulmonary function and cardiac risk factors.

If a patient with a TAAA 6 cm or greater has adequate pulmonary reserve ($FEV_1 > 70\%$ predicted) and low cardiac risk, an open surgical repair is the definitive primary treatment option. However, if a patient were determined to be at low risk from a pulmonary standpoint but felt to be at high risk from a cardiac perspective, then continued observation is usually recommended. If the patient exhibits continued growth of the aneurysm or has direct aneurysm-related symptoms, appropriate cardiac revascularization is indicated prior to any type of direct surgical intervention for the TAAA [see Figure 6].

In patients with poor pulmonary function ($FEV_1 < 70\%$ predicted) on pulmonary function testing and relatively low cardiac risk, then an option that is possible is a debranching procedure followed by endograft repair.³¹⁻³³ Additional options include continued observation and a branched or fenestrated endograft. The latter treatment is available only in select centers, with very ill-defined results.^{34,35} Finally, in patients with poor pulmonary function who are determined

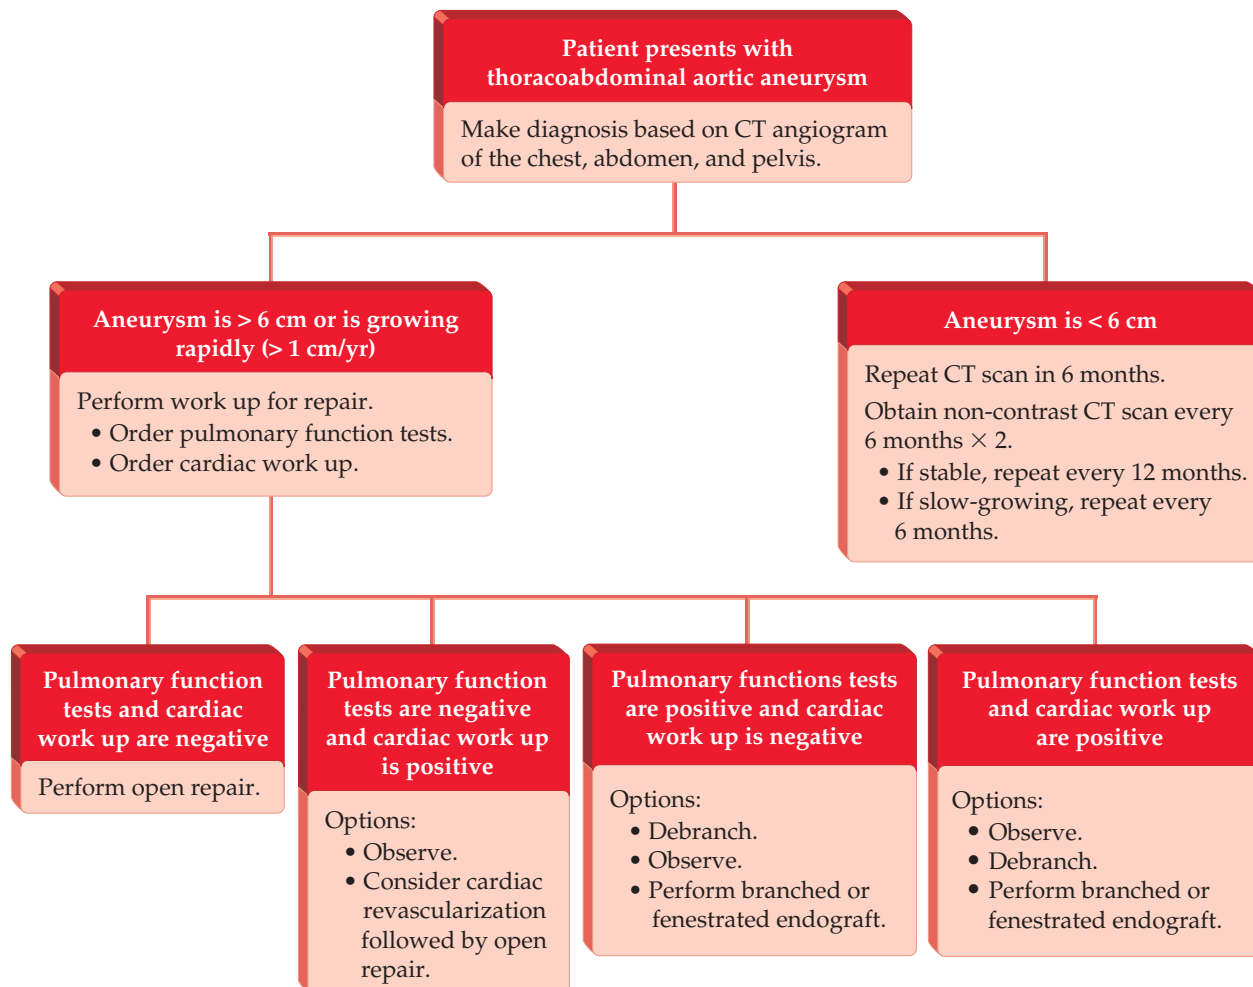

Figure 6 Evaluation of a patient with a thoracoabdominal aneurysm. CT = computed tomographic.

to be at high risk from a cardiac standpoint, the only option is observation [see Figure 6].

Open Repair

Despite improvements in surgical technique, surgical adjuncts, and perioperative care, open surgical repair of a thoracoabdominal aneurysm remains a morbid procedure involving entering two major body cavities and can be a daunting endeavor for both the surgeon and the patient. Successful repair of TAAAs was first reported in the 1950s, and in 1993, Svensson and colleagues' benchmark series describing their experience with 1,509 patients undergoing TAAA repair was published.¹⁷ In this cohort, there was an 18% incidence of postoperative renal failure (9% requiring hemodialysis) and a 16% rate of paraplegia or paraparesis. Factors associated with increased rates of SCI, paraplegia, or paraparesis were extensive replacement of the aorta, increased age of the patient, preoperative rupture, presence of a proximal aortic aneurysm, presence of preoperative renal dysfunction, and increased aortic cross-clamping time. In this study, the mean total aortic cross-clamping time, defined as the time to reestablishment of flow to the lower limbs, was 43 minutes. When the aorta was clamped for less than 30 minutes, paraplegia was rare,

but when the duration of cross-clamping was longer than 60 minutes, the risk of SCI was substantially higher. Additionally, in this study, it was demonstrated that morbidity and mortality of TAAA repair increased in relation to the extent of the aorta replaced, with repair of type II TAAA having the highest rate of mortality (9.7%), followed by SCI (31.5%), bleeding requiring reoperation (9.5%), and renal failure requiring hemodialysis (10.4%).

Over the last several decades, results of thoracoabdominal aortic operations have improved considerably because of improved surgical technique, anesthesia care, and postoperative or intensive care unit (ICU) care. Additionally, specific adjuncts directed at the major complications associated with TAAA repair have been used to decrease the morbidity (in particular, SCI and renal failure) and mortality associated with this procedure.³⁶⁻³⁸

Adjuncts directed at decreasing the rates of SCI have included cerebrospinal fluid (CSF) drainage, reimplantation of key intercostal vessels, regional hypothermia and epidural cooling, pharmacologic interventions, and distal aortic perfusion. CSF drainage, intraoperatively and postoperatively, is used to decrease the risk of SCI and delayed neurologic deficits by helping to maintain the perfusion pressure seen

by the spinal cord. Spinal cord perfusion pressure is defined as the difference in the mean arterial pressure and the CSF pressure. It is conceptually the same as cerebral perfusion pressure, with the idea of maintaining adequate spinal cord perfusion through a combination of keeping the CSF pressure low, through CSF drainage, and maintaining an adequate mean arterial pressure, through the use of vasopressors if needed. Spinal cord swelling has been implicated as a cause of delayed neurologic deficits³⁹ and provides support to the practice of continuing CSF drainage for 48 to 72 hours postoperatively. Additionally, a randomized clinical trial by Coselli and colleagues evaluating the use of CSF drainage showed significantly reduced rates of paraplegia with CSF drainage intraoperatively and for 48 hours postoperatively.⁴⁰ In this study, 145 patients with type I or type II thoracoabdominal aneurysms underwent open repair after randomization to intraoperative and postoperative CSF drainage or no CSF drainage. The patients were then all treated with a consistent approach of heparinization, permissive mild hypothermia, distal aortic perfusion, and reimplantation of critical intercostal arteries. In the patients randomized to CSF drainage, it was started in the operating room and continued for 48 hours postoperatively with a target CSF pressure of 10 mm Hg or less. In the control group, 13% of patients had paraplegia or paraparesis, whereas only 2.6% of the patients in the CSF drainage group did, representing an 80% reduction in the relative risk of postoperative deficits.

When replacing the descending thoracic aorta, the blood supply to the spinal cord is disrupted and the risk of SCI is increased when key intercostal vessels at the levels of T9 to L1 are not reimplanted. Cambria and colleagues showed a

10-fold increased risk of SCI in the repair of type I or II TAAA when the intercostal vessels at the levels of T9 to L2 were not preserved.⁴¹ Similarly, multiple other studies have documented the increased risk of SCI with the sacrifice of intercostal vessels in the critical T9 to L1 levels.^{42–44} A general approach to management of patent intercostal vessels, particularly in the repair of type I and II TAAA, aimed at minimizing the risk of SCI is to ligate vessels at the levels of T8 and above while aggressively reimplanting those at the T9 to L1 levels, thereby minimizing the risk of ischemia in this important watershed distribution.

Regional hypothermia with epidural cooling has been advocated by many others as a principal adjunct to prevent SCI. The target area of the spinal cord cooling is the T9 to L1 levels, in particular where the spinal cord blood flow may be marginal. To achieve regional hypothermia, particularly during aortic cross-clamping, when it is at greatest risk for SCI, an epidural catheter is inserted at the T10 to T12 levels and advanced cephalad a short distance. A second single-lumen intrathecal catheter for the measurement of CSF temperature and pressure is then placed at the L3 to L4 levels. Epidural spinal cord cooling is achieved with the infusion of iced saline (4°C) into the epidural space to allow continuous cooling of the adjacent tissue, thereby lowering the metabolic demands of the nervous tissue and risk for ischemic injury [see Figure 7]. Epidural cooling is used primarily for the repair of type I and II TAAA and has been shown to significantly reduce the risk of SCI in this high-risk group of patients,^{36,37} as well as reduce the number of days in the ICU, with a trend toward improved survival.³⁶

Pharmacologic agents aimed at limiting excitatory mechanisms that can contribute to ischemic injury have been investigated

Figure 7 Regional spinal cord hypothermic protection is achieved via epidural cooling. A 4°C epidural saline infusion (arrow) is begun in anticipation of cross-clamping. Cerebrospinal fluid temperature and pressure are simultaneously monitored with a separate intrathecal catheter.

extensively. The use of naloxone, a pharmacologic inhibitor of excitatory neurotransmission, has been evaluated in clinical trials and has been shown to decrease spinal cord metabolism and, in combination with CSF drainage, decrease the incidence of SCI,⁴⁵ leading some centers to use these modalities in combination during the perioperative period.

Early in the experience with the repair of TAAA, the effect of prolonged aortic cross-clamping time on SCI and the need to minimize cross-clamping time were emphasized by Svensson and colleagues.¹⁷ The importance of cross-clamping duration becomes less clear and perhaps less important in centers where distal aortic perfusion methods are used routinely^{46,47} as this maintains perfusion to the spinal cord through important routes of collateral circulation. Coselli and colleagues compared the rates of SCI in patients operated on for TAAA with left heart bypass (LHB) and distal aortic perfusion [see Figure 8] with those in patients undergoing TAAA repair without LHB and found a significant difference in the two groups.⁴⁶ Lower rates of SCI despite longer cross-clamping times were observed in the LHB group.⁴⁶ When distal aortic perfusion is combined with CSF drainage, the incidence of neurologic deficits for all aneurysm types is reduced to 3.3% from 8.4% when these adjuncts are not used. This is particularly evident with the higher-risk type II TAAAs, in which the incidence of neurologic deficit was 7.8% with these adjuncts and 30.6% without.⁴⁸ Theoretical benefits of distal aortic perfusion include maintenance of spinal cord perfusion through collateral circulation, reduction of proximal hypertension, reduced cardiac ischemia, and decreased cardiac afterload.

In addition to preventing SCI, retrograde perfusion of the celiac axis, superior mesenteric arteries, and both renal arteries with cold blood (celiac, superior mesenteric, and right renal arteries) or cold lactated Ringer solution (left renal artery) can reduce end-organ dysfunction and decrease the risk of postoperative renal failure.

At our institution, a patient with a TAAA greater than 6 cm has good pulmonary function and limited cardiac risk and is offered open repair after careful and deliberate consultation, explaining all of the possible outcome morbidities. Prior to the actual operation, after insertion of appropriate lines and a lumbar drain, the patient is positioned in the right lateral decubitus position (with sandbag support) with the hips slightly turned to allow access to both groins. The extent of the incision is tailored to fit the extent of the aneurysmal disease. The full thoracoabdominal incision begins posteriorly between the tip of the scapula and the spinous process. It curves along the sixth intercostal space to the costal cartilage, then obliquely to the umbilicus, and finally in the midline to above the symphysis pubis. After division of the latissimus dorsi and serratus anterior muscles, the left chest is entered following deflation of the left lung. Resection of the sixth rib (or a trapdoor rib flap) is commonly done for TAAA repair as it facilitates exposure, although this is not usually necessary for repair of a type IV aneurysm. Sometimes, depending on the proximal involvement, a type IV aneurysm can be approached through a retroperitoneal incision with division of the diaphragmatic crus and avoidance of a full thoracoabdominal incision. Likewise, a modified thoracoabdominal incision ending at the costal cartilage or above the umbilicus can be used, which provides excellent exposure for surgery involving a type I TAAA if the aneurysm ends above the superior mesenteric artery.

All open repairs of TAAA are performed with the aid of cardiac anesthesiology and dual-lumen endotracheal tube intubation to facilitate entrance into the left thoracic cavity. All patients receive CSF drainage intraoperatively and postoperatively for 48 to 72 hours. In the ICU, the drain is opened to air and placed at a levels of 10 cm above the lumbar spine to maintain a CSF pressure less than or equal to 10 mm Hg. Naloxone is administered as a continuous infusion at 1 µg/kg/hr started before induction and continued for 48 hours after surgery.

In addition to these adjuncts, for all types of TAAA, the repair is performed with distal aortic perfusion using a left atriofemoral bypass and a Biomedicus centrifugal roller pump [see Figure 8]. The clamp and sew technique is used at our institution only if it is not possible to clamp the distal aorta at any levels.

Debranching and TEVAR

An alternative to open surgical repair of TAAA is a hybrid approach involving open visceral arterial bypass, or visceral vessel debranching, followed by endovascular repair of the thoracoabdominal aorta [see Figure 9]. Because the thoracic cavity is not entered, nor is the aorta cross-clamped, the theoretical advantages are apparent. It is thought that this would lead to fewer pulmonary complications and be less stressful physiologically on patients, allowing many patients to undergo repair that previously would have been unfit for open repair, particularly from a pulmonary standpoint. The patient population with thoracoabdominal aneurysms overall is a group with multiple comorbidities: rates of moderate to severe COPD of 29 to 48%, coronary artery disease in the range of 31 to 53%, and preoperative renal insufficiency between 12 and 14%^{17,37,44} have been reported. The earliest reports of small series and case reports had promising results, with perioperative mortality between 0 and 13% and no reported paraplegia.^{31–33} This procedure has generally been done in patients felt to be at too high of a risk for open repair, with the idea that this two-staged approach would be less invasive and more easily tolerated. Subsequent reports have shown perioperative mortality in the range of 14 to 23%, with paraplegia rates as high as 11 to 15%,^{18,49} whereas others have reported mortality as high as 25% for the visceral bypass or first stage of the operation, exclusive of the endografting.⁵⁰ These latter results suggest that the staged or hybrid approach to repair of thoracoabdominal aneurysms may not be the truly less invasive approach that was anticipated.

At our institution, we use the option for visceral artery debranching followed by endografting of the TAAA as the first treatment option for patients with inadequate pulmonary function (FEV₁ less than 70% of predicted) to undergo open repair but who are at relatively low cardiac risk. The patients are taken to the operating room for the visceral vessel revascularization, given a period of 1 to 2 days to recover physiologically from this operation, and then taken back for the TEVAR procedure. This approach is generally reserved for patients felt to be too sick to undergo open repair, and although the morbidity and mortality overall have been similar to those for open repair, these early results are somewhat encouraging in this higher-risk population. Larger studies and longer follow-up are still needed to determine what the long term efficacy of this approach will be.

Complete Endovascular Repair of TAAA

In an attempt to ameliorate the risks of conventional TAAA repair and expand the range of patients who are amenable to treatment of TAAA, another approach is an entirely endovascular approach. This has been described with two different types of devices. The first type uses fenestrations, preplaced holes in the fabric that are positioned in alignment with the orifices of the visceral arteries. They are then adjoined to the respective visceral arteries with a balloon-expandable stent graft. The second involves aortic endografts to which fabric branches are attached. The branches are then fixed to the visceral vessels with self-expanding stent grafts [see Figure 10].

Fenestrated grafts used to treat TAAA have a nitinol ring sutured around the orifice of each fenestration. This creates a rigid location to which a balloon-expandable stent graft can be attached, allowing one to treat aneurysms involving the visceral arteries. The mating stent graft is advanced into the target vessel an adequate length and deployed, forming a bridge between the aortic stent graft and visceral vessel. The aortic component of the mating stent graft is then dilated with a larger balloon to create an hourglass-type seal against the nitinol ring. Using this technique to treat TAAA was initially described by Anderson and Adam in 2005.⁵¹

Attaching a branch to the endograft provides a segment of overlap that can be used to attain a better sealing zone and fixation [see Figure 10]. Additionally, it allows the use of self-expanding stent grafts, which may allow for the ability to accommodate tortuosity and diameter discrepancy. In this setup, the aortic device is deployed above the target vessel; the branches are then cannulated with a wire from a

brachial approach. The wire is then used to cannulate the target visceral artery, and mating self-expandable stents grafts are deployed to join the target vessel and aortic graft. Advantages of branched grafts over reinforced fenestrations include improved mating stent graft joint integrity. One disadvantage of branched endografts relates to the need to achieve an aortic seal well above the branch origin, which may require coverage of nondiseased aorta and increase the risk of paraplegia.⁵²

Use of this modality to treat TAAA in the United States has been isolated to several highly specialized centers. A report out of the Cleveland Clinic in 2007 documented their experience over 21 months in which 73 patients underwent endovascular repair for TAAA.³⁴ The majority of repairs, 45 patients, were done for type IV TAAA, whereas the other 28 patients were treated for type I, II, or III TAAA. The aneurysms were successfully excluded in 93% of the patients, with no conversions to open surgery and no ruptures. Thirty-day mortality was 5.5%, and the paraplegia rate was 2.7%. They did, however, have an overall incidence of endoleaks of 11% noted prior to discharge, but the majority were treated successfully with secondary endovascular intervention. The authors noted no ruptures or cases of aneurysmal sac enlargement at 12 months of follow-up and concluded that endovascular repair of aortic aneurysms involving the visceral segment in nonsurgical candidates is feasible, with relatively low morbidity and mortality in the high-risk patient population studied. Another recent report out of the University of California-San Francisco documented their experience in treating 22 patients with TAAA with branched endografts.³⁵ Each endograft was manufactured

Figure 10 (a and b) Examples of a branched endograft. (c) Reconstruction of a postoperative computed tomographic scan following totally endovascular repair of a type II thoracoabdominal aortic aneurysm.

for the patient, with the caudally directed cuffs positioned to correspond to the location of the arterial branch on the native aortic aneurysm based on dimensional analysis of fine-cut contrast-enhanced CT scans. CSF drainage was used during the procedure and in the early postoperative period. The patients had a perioperative mortality of 9.1%, and the authors noted that renal failure, myocardial infarction, stroke, and paraplegia did not occur in any of the surviving patients. They concluded that their experience suggests that multibranched stent graft implantation is safe, feasible, effective, and applicable in a high proportion of cases and that it supports an expanded role in the treatment of TAAA.

Although the early results are promising, the endovascular repair of TAAA remains a technically demanding modality that at the current time is feasible at a few centers across the country. Longer-term follow-up is needed to determine the durability of this repair and how widely applicable it will become in the future.

Summary

Endovascular treatment of descending thoracic aneurysms is safe and technically feasible. Early, mid-, and longer-term outcomes compare favorably with those of open surgical repair, with the morbidity and mortality attributable to cardiac complications, pulmonary complications, and paraplegia

clearly less common with endovascular repair. At our institution, endovascular repair of isolated DTAs has become the treatment modality of choice.

Treatment of TAAA continues to be a difficult and morbid endeavor. Open repair of TAAA in patients who are physiologically fit enough to undergo repair remains the best option. In patients undergoing open repair, adjuncts such as distal aortic perfusion, CSF drainage, epidural cooling, reimplantation of key intercostal vessels, and intraoperative perfusion of visceral vessels are used to minimize the morbidity and mortality of the operation. Debranching procedures followed by endografting are an option in patients whose pulmonary function makes standard open repair a prohibitive risk. Initially, the hybrid procedures were felt to be a less morbid approach in this high-risk patient population; however, recent reports suggest that the results with this approach may be more morbid than previously thought. Totally endovascular repair of TAAA is a developing technology currently isolated to a few highly specialized centers. This technology will continue to grow and expand, and the longer-term results that will come will determine the degree of applicability.

31 COMPARTMENT SYNDROME

Neha D. Shah, MD, and Joseph R. Durham, MD, FACS

Disease Definition

Management of compartment syndromes is a vital tool to have in the surgeon's armamentarium. Understanding of the etiologic mechanisms, along with a thorough knowledge of the pertinent pathophysiology and anatomy, will result in timely recognition and treatment. Decreased morbidity and improved patient function are the desired outcomes. Failure to address a compartment syndrome can lead to permanent neurologic damage, loss of function, amputation, and even severe metabolic derangements, leading to permanent renal failure and cardiorespiratory compromise.

Compartment syndrome is defined as an elevation of the interstitial pressure in a closed fascial compartment that results in microvascular compromise. Compartment syndromes can develop anywhere skeletal muscle or abdominal organs are enveloped by a rigid, unyielding fascial layer. Compartments with relatively noncompliant fascial boundaries are most commonly involved, especially the anterior and deep posterior compartments of the leg and the volar compartment of the forearm. Other sites include the buttock, thigh, foot, arm, hand, paraspinal muscles,¹ and abdomen. Increased pressure within these musculoskeletal compartments can result in relative ischemia with neurologic and soft tissue compromise. Once a given increased pressure threshold is reached, arterial perfusion of the soft tissues is diminished, resulting in ischemic damage to the vulnerable nerves and muscles. This can lead to neurologic injury, muscle necrosis, scarring, and contractures. In addition to the local tissue damage, release of abnormal metabolic products can cause significant cardiorespiratory and renal compromise.

Timely diagnosis of a developing or existent compartment syndrome can be a challenging problem. Although such recognition is often straightforward in the awake, alert patient, it can be most difficult in the patient with altered mental or neurologic status, such as a patient already under general or regional anesthesia, a comatose or obtunded patient, a patient with a peripheral nerve injury, a spinal cord injury patient, or a patient under the influence of drugs.

Epidemiology

Compartment syndromes are classified as acute or chronic depending on the etiology of the insult. Acute compartment syndromes typically result from orthopedic or vascular trauma. They may also occur during or following acute ischemic events such as acute arterial thromboembolism, popliteal artery aneurysm thrombosis, or reperfusion following correction of profound limb ischemia. Chronic compartment syndromes are not the result of acute injury or ischemia. They tend to occur in healthy active individuals, resulting

from increased compartment pressures during repetitive vigorous exertion. Usually occurring in athletes, this chronic syndrome typically involves the leg or the forearm.^{2,3} Chronic exertional compartment syndromes (CECSs) are discussed in more detail below.

There are three basic mechanisms leading to an acute compartment syndrome: increased tissue pressure within the enclosed space, extrinsic compression on the compartment, and decreased volume of the involved compartment. The presence of an existing or a developing acute compartment syndrome is the typical indication for a fasciotomy procedure. Another indication is a clinical situation in which the incipient development of a significant compartment syndrome is very likely, such as prolonged extremity ischemia or combined extremity arterial and venous injuries (especially the popliteal vessels and ligation of the popliteal vein). Other clinical situations that may result in an acute compartment syndrome include severe burns and prolonged limb compression following loss of consciousness from a drug overdose or a stroke. Delayed development of an acute compartment syndrome is common and may be very difficult to document, especially in the patient with altered mental status or the trauma patient with multiple injuries. Development of a compartment syndrome may occur beyond 48 hours after the initial injury.

The most common cause of the development of an acute compartment syndrome is a bony fracture, especially the tibia; the resultant hemorrhage, soft tissue injury, and edema can lead to increased compartmental pressures. Consequently, these are managed by the orthopedic surgeons in most institutions. Arterial bleeding into rigid, fixed compartments, reperfusion following prolonged extremity ischemia attributable to arterial injury (traumatic or iatrogenic), embolic disease, popliteal aneurysm thrombosis, and failure of an existing bypass often result in compartment syndromes. Not surprisingly, compartment syndrome following penetrating trauma is often attributable to direct vascular injury with resultant ischemia and reperfusion injury; associated soft tissue injury compounds the problem. Blunt trauma typically results in compartment syndrome as a result of musculoskeletal injury or direct tissue damage. Development of a clinically relevant compartment syndrome following elective extremity revascularization for chronic extremity ischemia may occur but is distinctly uncommon.

Another common cause of an acute compartment syndrome is reperfusion of an ischemic limb following an acute thromboembolic event or repair of a vascular injury, especially if the ischemia is profound and exceeds 6 hours. The combination of arterial and venous injuries significantly increases the risk of developing this disorder. Iatrogenic extravasation of intravenous fluids into a compartment can result in increased compartmental pressures, especially if the

infused agent is caustic to the local tissues. Increased edema and compartment pressures can also result from electrical or thermal injuries, especially if associated with rigid, circumferential eschars. Venous outflow obstruction from advanced deep vein thrombosis can result in phlegmasia cerulea dolens, increased compartmental pressures, and venous gangrene; this is usually associated with a malignant process or other hypercoagulable state.

Extrinsic compression of muscle compartments can also result in significant compartment syndromes. First recognized during the bombing of Britain during World War II, crush injuries from being trapped in the rubble led to muscle compromise from the unyielding weight of collapsed building materials; those lucky enough to survive the initial insult often died from renal failure resulting from myoglobinemia as a consequence of the muscle ischemia. Although still occurring in combat and earthquake casualties, this extrinsic compression mechanism is more often seen in the comatose drug overdose victim who collapsed on a hard floor surface for many hours before discovery and rescue. Unfortunately, this mechanism can also affect the elderly person with prolonged immobility on the floor after a fall or stroke. A preventable iatrogenic cause of compartment syndrome from extrinsic pressure is inadequate padding of vulnerable pressure points during a prolonged surgical procedure under general or regional anesthesia. Finally, compartment syndromes can result from extrinsic compression from burn eschars, tight casts, or constricting bandaging.

Pathophysiology

The pathophysiology of compartment syndrome involves an insult to normal local tissue homeostasis that results in increased tissue pressure, decreased capillary blood flow, and local tissue necrosis because of a lack of adequate oxygen delivery.³ Local tissue blood flow (LBF) is equal to the arteriovenous pressure gradient (Pa-Pv) divided by the local vascular resistance (R): $LBF = (Pa-Pv)/R$. In the usual setting, tissue ischemia results in vasodilation with decreased vascular resistance, leading to recruitment of increased blood flow. Elevated compartmental pressures can effectively shut down capillary flow, even in the patient with no intrinsic peripheral vascular disease. This can result in significant muscle necrosis if the intracompartmental pressure exceeds 30 mm Hg for more than 8 hours.³ Certainly, significant neuromuscular injury can be expected to occur in a shorter time frame in the settings of even higher compartment pressures, preexisting chronic ischemia from peripheral vascular disease, hypovolemic shock from trauma, cardiogenic shock, or severe soft tissue damage from a crush injury.

Compartment syndrome results from inadequate perfusion of the soft tissues; this process begins when the pressure within the compartment meets or exceeds the perfusion pressure within the capillary beds of the nerves and muscles. Normal compartment tissue pressures range from 0 to 10 mm Hg. Arteriolar and capillary blood flows are very sensitive to changes in compartment pressures. Critical closing pressures have been shown to be 21 mm Hg in the leg and 33 mm Hg in the arm.⁴ When the compartment pressure exceeds these values, arterial perfusion is reduced, resulting in ischemic changes. In the patient with systemic hypotension, compartmental pressures as low as 20 to 40 mm Hg can

result in diminished tissue perfusion and tissue injury. At this point, microcapillary flow ceases and the onset of anaerobic metabolism begins, resulting in lactic acidosis. Inflammatory mediators are activated, and free radicals are released. Cellular damage ensues. Neutrophils are recruited and adhere to vascular endothelium, stimulating the release of more free radicals and proteases. The inflammatory mediators cause cell wall lipid peroxidation, which, in turn, increases basement membrane permeability. Leakage from capillaries further increases tissue edema and, therefore, tissue pressure. This sets in play a vicious cycle of progressive muscle edema, actual closure of the capillary beds, increased capillary permeability, and further soft tissue swelling. Eventually, the pressure becomes great enough to reduce arterial inflow and mechanically compress veins and nerves, resulting in nerve injury and myonecrosis; rarely does the compartment pressure increase sufficiently to compress major arteries. Hence, the patient's pulses will usually remain intact during the development of compartment syndrome.

Diagnosis

The diagnosis of a compartment syndrome is based on clinical suspicion, the mechanism and location of injury, physical examination findings, and objective compartment pressure measurements [see Figure 1]. It cannot be overemphasized that a high level of suspicion must be held for compartment syndrome, especially in trauma victims and patients with vascular disease undergoing revascularization. The clinical presentation may be subtle in the early stage of compartment syndrome, but early diagnosis is critical so that therapy can be initiated prior to the onset of irreversible tissue ischemia.

The most important initial symptom is pain out of proportion to that expected from the injury. Severe tenderness and pain on passive stretching of the musculature are also suggestive of an existing compartment syndrome. Possible neurologic findings are hypesthesia, paresthesia, or decreased motor function (e.g., peroneal nerve involvement and decreased foot dorsiflexion). Diminished sensation in the distribution of relevant nerves within the compartment in question may be an early finding attributable to ischemia of the nerves [see Table 1 and Table 2]; sensory loss usually precedes any compromise of motor function. The neurologic sensory examination should include testing with pinprick, light touch, and two-point discrimination. These diminished sensory findings are often the first abnormality noted with a developing compartment syndrome. Muscle weakness with eventual paralysis follows if the compartment is not promptly released.

These findings are often straightforward and readily evident in the awake and alert patient. The diagnosis of compartment syndrome is straightforward and is based on physical findings and the mechanism of injury. Diagnosis is much more challenging in the patient with an altered mental state or neurologic deficit, as may be seen with alcohol or drug influence, general or regional anesthesia, spinal cord injury, peripheral nerve injury, or unconsciousness. In these instances, compartment pressure measurements are invaluable in the decision-making process. Diagnosis may

Figure 1 The algorithmic approach to management of compartment syndrome. MAST = military anti-shock trousers; DVT = deep vein thrombosis.

also be quite difficult in the young child as a result of agitation, fear, communication challenges, and lack of cooperation. Appropriate pressure analysis can prevent unnecessary procedures and, at the same time, allow appropriate timely action when a compartment syndrome is documented.

Physical examination findings suggestive of an advanced acute compartment syndrome typically include rigidity and tenderness of muscles in the involved compartment, pallor or mottling of the skin, or neurologic motor deficits. Loss of arterial pulses may be a late sign but is more likely

Table 1 Contents and Function of the Compartments of the Leg

Lower Leg Compartment	Muscles	Arteries	Nerves	Motor Function	Sensory Innervation
Anterior	Tibialis anterior Extensor hallucis longus Extensor digitorum longus Peroneus tertius	Anterior tibial artery	Deep peroneal nerve	Toe extension Foot inversion and dorsiflexion	Webpace between great and second toes
Lateral	Peroneus brevis Peroneus longus	—	Superficial peroneal nerve	Foot dorsiflexion Foot eversion	Dorsal foot
Superficial posterior	Gastrocnemius soleus plantaris	—	Sural nerve	Foot plantar flexion Knee flexion	Lateral foot
Deep posterior	Popliteus Flexor digitorum longus Flexor hallucis longus Tibialis posterior	Posterior tibial artery Peroneal artery	Posterior tibial nerve	Toe flexion Foot plantar flexion Foot eversion	Sole of foot

attributable to a concomitant arterial injury rather than a compartment syndrome. An elevated serum creatine phosphokinase is an ominous finding signifying late diagnosis and established myonecrosis. Myoglobinuria and resultant renal failure add to the morbidity and mortality of this disorder.

Unfortunately, these findings are all nonspecific, and none are diagnostic for an established, significant compartment syndrome. If a compartment syndrome is suspected and the physical findings are not reliable, one should proceed directly with measurement of the intracompartmental pressures. The original technique described by Whitesides in 1975⁵ using intravenous tubing, a three-way stopcock, and a mercury manometer was a significant advance but is cumbersome and not as reliable as more current techniques. Continuous monitoring of compartment pressures can now be accomplished using wick catheter monitors or slit catheters.³ These have the advantage of providing continuous real-time pressure values

but monitor only one compartment per catheter. This approach is particularly useful in the setting of ongoing serial examinations such as might be seen in the burn patient with progressive tissue injury and significant constricting eschar formation. In the acute setting, our preference is to proceed with direct pressure measurements of the involved compartments using the Stryker intracompartmental pressure monitoring system (Stryker Surgical, Kalamazoo, MI). This direct approach allows serial measurements at multiple sites and has been very easy, quick, reasonably reliable, and reproducible. Noninvasive assays exist to assist in the determination of an acute compartment syndrome but are still in the development stage and not widely used; these tend to have a high specificity but a low sensitivity for reliable diagnosis. A surgical philosophy that blends a high index of clinical suspicion, serial examinations, and measurement of compartment pressures will yield excellent clinical outcomes.

Table 2 Contents and Function of the Compartments of the Forearm

Forearm Compartment	Muscles	Arteries	Nerves	Motor Function	Sensory Innervation
Volar	Pronator teres Flexor carpi radialis Palmaris longus Flexor carpi ulnaris Flexor digitorum superficialis Flexor digitorum profundus (pronator quadratus)	Radial artery Ulnar artery	Median nerve Ulnar nerve	Forearm flexion Forearm pronation Wrist flexion Digit flexion	Palm of hand

Measurement of compartment pressures is relatively easy now with the above devices. However, interpretation of the pressure measurements merits further discussion. Three different values are available to define the significance of the pressures and guide the decision-making process: (1) the absolute compartment pressure value, (2) the delta pressure, and (3) the compartmental perfusion pressure.

Normal compartment tissue pressures range from 0 to 10 mm Hg. Measurement of the absolute pressure in the compartment is easy, is reproducible, and can be obtained serially and in various locations within the given compartment. An absolute pressure measurement over 30 mm Hg is considered abnormal but is not necessarily a fail-safe value to mandate fasciotomy. It still remains, however, a common threshold to recommend fasciotomy. Concern for a compartment syndrome and the consideration of a fasciotomy intervention occur when the absolute compartmental pressure reaches 30 mm Hg or greater, especially if the patient has signs and symptoms or if the patient cannot be reliably examined. Some authorities have shown that, with close serial observation, the fasciotomy procedure may be reserved for absolute pressures exceeding 45 mm Hg in the alert patient with no worrisome signs or symptoms. Unfortunately, there is no specific threshold pressure above which compartment syndrome always occurs. Other factors may come into play, such as the duration of compartmental hypertension, preexisting peripheral arterial disease, systemic hypotension, shock, and coexisting tissue injury. These parameters may lower the threshold for action.

To address this shortcoming, two other values have been defined and are outlined below. A dynamic compartmental pressure threshold relative to the diastolic blood pressure or the mean arterial blood pressure is probably a more appropriate and reliable index for proceeding with fasciotomy.⁶ The degree of tissue perfusion has been shown to correlate with the diastolic blood pressure; when the pressure within a compartment exceeds the diastolic blood pressure, arterial perfusion ceases. Compartmental pressures capable of compromising tissue perfusion appear to occur when they rise to within 20 mm Hg of the diastolic blood pressure or to within 30 mm Hg of the mean arterial pressure.

Consequently, some clinicians rely on the comparison of the compartment pressure to the diastolic blood pressure. Delta pressure is defined as the diastolic blood pressure minus the measured compartment pressure. This approach is supported by the observation that relative hypertension may be protective against the development of a compartment syndrome. Therefore, some clinicians advocate the use of the delta pressure to guide timing of a fasciotomy. When the compartment pressure rises to within 30 mm Hg of the diastolic blood pressure, capillary blood flow is compromised and serious consideration should be given to performing a prompt fasciotomy. A delta pressure value between 10 and 30 mm Hg has been recommended as the threshold for surgical intervention.⁴

Finally, the concept of compartmental perfusion pressure (also known as the delta mean arterial pressure) probably yields the most accurate assessment of the impact of increased compartmental pressures on actual tissue perfusion. This value is defined as the mean arterial pressure minus the measured compartment pressure. Capillary blood flow ceases

when the compartmental perfusion pressure is 25 mm Hg or less.⁴ Therefore, a value less than 40 mm Hg is the recognized threshold to proceed to fasciotomy. This approach takes into account variances in perfusion related to systemic hypotension and is particularly helpful in the trauma patient. This is probably the most reliable pressure measurement assessment currently available and the one recommended in most busy clinical practices.

If a fasciotomy is not performed right away, serial pressure measurements are essential as the development of a compartment syndrome may be progressive and insidious. Delayed development of a compartment syndrome is common and may be very difficult to document, especially in the patient with altered mental or neurologic status or in the trauma patient with multiple injuries. Although uncommon, the onset of a compartment syndrome may occur as late as 48 hours after the initial injury.

Pressure within a given compartment is not always uniformly distributed and tends to be higher in the region of injury. Consequently, special attention is given to pressure measurements in the immediate vicinity of a known injury or an area of clinical concern. Measurement of the compartment pressures should be obtained with the limb gently supported as pressure on the limb from an underlying hard surface (e.g., operating room table) may lead to falsely elevated pressure measurements. Pressure measurements can be inaccurate in up to 27% of acute limb trauma patients, so compartment pressure measurements should be used as an adjunct to physical examination and clinical suspicion, not as the sole determinant of the need for fasciotomy.³ Unfortunately, there is no specific absolute pressure threshold for a compartment syndrome. Consequently, the final decision to proceed with a fasciotomy rests on clinical judgment and experience.

Management

Once a compartment syndrome has been diagnosed, immediate decompression is essential. While preparing the patient for the surgical procedure, several supportive measures should be implemented. Removal of all external compression, such as dressings, casts, or splints, is advised. The involved limb should be placed at the level of the heart, not elevated. Supplemental oxygen can also be helpful, along with appropriate volume loading with intravenous fluids to increase or maintain a high-normal blood pressure. If myonecrosis is suspected or already present, renal protection with sodium bicarbonate and stimulation of a brisk diuresis with fluids and mannitol may minimize damage to the kidneys. Finally, hyperkalemia must be addressed with loop diuretics and glucose or insulin challenge to achieve prompt serum potassium reduction. Life-threatening hyperkalemia may even require emergent hemodialysis.

A properly timed, expertly performed fasciotomy procedure is an invaluable tool to have in the surgeon's armamentarium. Knowledge of the appropriate indications, as well as the anatomy involved, will lead to decreased patient morbidity and enhanced functional outcomes. Fasciotomy is performed to treat existing or developing compartment syndromes; the most common anatomic sites for fasciotomy are the leg and forearm. This is because of the well-defined, rigid fascial boundaries of these locations and the frequency

of injury to the distal extremities. Other less common sites for fasciotomy include the arm and the thigh.⁷ Compartment syndromes involving the hand,⁸ foot,^{9–11} shoulder, lumbar paraspinal muscles, and spinal cord also exist but are not addressed herein.

There are four essential components to the optimal functional outcome following a fasciotomy procedure. First, the overlying skin must be completely incised as it can function as a constricting envelope to contribute to persistently elevated compartment pressures, even with an adequate fascial release. Second, the fascia along the entire length of the incision must be incised to allow full decompression. Third, local wound care of the open incisions will hasten prompt healing and help minimize morbidity. Daily inspection and local débridement of nonviable tissues as needed are crucial. Reestablishment of healthy skin coverage with local wound measures, partial-thickness skin grafts, or the use of negative pressure therapy completes the wound healing process. Finally, timely aggressive physical therapy will help rehabilitate the patient and facilitate return to optimal function levels.

Intraoperative assessment of the completeness of fasciotomy is largely visual. The surgeon must be certain that all involved compartments are completely decompressed and that all muscle compression has been released. Muscle bellies should appear viable with normal coloration. Discolored, obviously necrotic tissues should be débrided. Questionably viable muscle should probably be left intact and reexamined in the operating room 24 to 48 hours later at the time of a dressing change. If distal pulses were not present preoperatively, they should be reexamined following fasciotomy. Return of normal pulses documents successful compartmental decompression. However, the lack of pulses may be attributable to concomitant peripheral arterial occlusive disease, especially in the older patient; in this setting, failure to have palpable pulses after fasciotomy does not imply inadequate decompression. The most important parameter to document complete fasciotomy is the neurologic status of the limb. Return of motor and sensory deficits following fasciotomy proves complete decompression and portends an excellent functional outcome. Prolonged, profound ischemia may lead to a delay in return of neurologic function. Unfortunately, this assessment cannot be performed until the patient is awake and alert. Also, this is not possible to assess in the patient with a spinal cord or peripheral nerve injury.

Local complications following fasciotomy are frequent, even with timely intervention. **Complications that may arise from a fasciotomy procedure include wound and soft tissue infection, iatrogenic nerve injury, prolonged hospitalization, and malfunction of the leg venous pump mechanism.^{12,13} As outlined by Modrall, major amputations can occur in 5 to 21%, neurologic deficits in 7 to 36%, and wound complications in 4 to 38% of all patients treated appropriately.⁶ These complication rates are higher if the fasciotomy procedure is delayed more than 6 hours. Exposed orthopedic hardware must be covered with viable tissues at the time of fasciotomy; similarly, vascular bypass grafts must be placed beneath healthy muscle. These factors must be taken into account when planning the incisions used for the fasciotomy procedure.**

There may be some concern regarding wound healing problems and prolonged wound care issues following fasciotomy; this can lead to delay in proceeding with the fasciotomy procedure in the patient with equivocal findings. Although unquestionably some morbidity results from the fasciotomy procedure itself, the consequences and morbidity of a missed compartment syndrome and failure to perform a timely fasciotomy can be disastrous.¹⁴ We subscribe to the notion that if one contemplates performing a fasciotomy, it should be done. This is similar to the philosophy in the modern military trauma surgery setting.¹⁵ If a fasciotomy procedure is performed and a compartment syndrome is not present, the limb musculature is usually not swollen and the possibility of a delayed presentation has been averted. Delayed primary closure a few days later is usually possible without the need for skin grafts. This approach helps minimize both hospital stay and cosmetic issues.

Overall complication rates increase dramatically if the fasciotomy procedure is delayed more than 12 hours. Almost half of patients with delayed fasciotomy required major amputation and 92% had significant neuropathy.⁶ Unfortunately, if amputation is required, it often must be performed at a higher level because of a lack of healthy muscle for bone coverage and stump healing. Loss of the musculature within one or two compartments of the leg usually results in the ability to ambulate following rehabilitation efforts with intensive physical therapy and orthotics. Loss of the muscles with three or more leg compartments almost always results in a functionless limb; in this setting, an early amputation at a level sure to heal followed by aggressive prosthetic rehabilitation may yield independent ambulation.¹⁶ Long-term problems following fasciotomy may include exposed bone or tendon, numbness, dysesthesias, muscle herniation, malfunction of the calf muscle pump, and cosmetic issues.

Anatomy and Surgical Techniques

THE LEG

The leg has four compartments: the anterior, lateral, superficial posterior, and deep posterior. Each compartment has a significant nerve coursing through it: the deep peroneal nerve (anterior compartment), the superficial peroneal nerve (lateral compartment), the sural nerve (posterior compartment), and the posterior tibial nerve (deep posterior compartment) [see Figure 2]. Although the anterior compartment is most commonly involved, more significant damage and morbidity tend to result from involvement of the deep posterior compartment.

Certain types of clinical situations may predispose to the development of a leg compartment syndrome. Injuries to the proximal half of the below-knee arterial segment are the most common cause of the development of compartment syndrome from penetrating trauma of the lower extremity.^{17–21} Shock also predisposes to compartment syndrome.¹⁹

Three distinct surgical techniques are available for complete decompression of all four leg compartments. The most commonly employed is the dual-incision technique, which involves separate medial and lateral leg incisions. Two other approaches permit decompression through a single lateral incision. One involves actual resection of the fibula and is

Figure 2 Four-compartment fasciotomy of the leg—dual-incision technique. (a) Lateral leg incision. (b) Cross-sectional view of the decompression of the anterior and lateral compartments through the lateral leg incision. (c) Medial leg incision. (d) Cross-sectional view of the decompression of the superficial and deep posterior compartments through the medial leg incision.

probably of historical interest only. The other is a perifibular technique. These single lateral incision approaches may have some utility if preservation of the integrity of the skin of the medial leg is essential, such as the presence of a comminuted tibia fracture. A medial leg incision in this setting could convert a closed fracture to an open fracture, with attendant risk of infection. However, in most vascular surgery settings, the dual-incision approach is safer, faster, and more effective than the single-incision methods.

The single lateral incision four compartment leg fasciotomy is accomplished through a long incision in line with the fibula that extends from just distal to the head of the fibula down to several centimeters proximal to the lateral malleolus. If performed too far posteriorly, the anterior compartment may not be identified properly and not decompressed adequately. The skin and subcutaneous tissues are undermined anteriorly with care not to injure the superficial peroneal nerve in the proximal aspect of the incision. The intermuscular septum

is identified, and a longitudinal fasciotomy of each of the anterior and lateral compartments is performed for the entire length of the incision. The skin and subcutaneous tissues are then undermined posteriorly to gain access to the superficial posterior compartment, which is released. Then the interval between the lateral and superficial posterior compartments is defined and separated. This exposes the flexor hallucis longus muscle, which is dissected off the fibula and retracted posteromedially, along with the peroneal vessels. Finally, the fascial attachment of the posterior tibial muscle to the fibula is cut longitudinally to allow decompression of the deep posterior compartment.

 The dual-incision technique is accomplished through two vertical skin incisions that are separated by a bridge of skin at least 8 cm wide [see Figure 2]. The first incision is along the lateral aspect of the leg centered over the interval between the anterior and lateral compartments, extending from the head of the fibula down to just above the lateral malleolus. The incision should be halfway between the crest of the tibia and the fibula. The intermuscular septum is identified. The fascia overlying the anterior compartment is divided 1 cm in front of the intermuscular septum along the entire length of the incision with care not to injure the superficial peroneal nerve in the proximal portion of the incision. The fascia of the lateral compartment is then divided 1 cm behind the intermuscular septum distally to include the extensor retinaculum at the lateral malleolus and proximally up to the origin of the muscles. The extensor tendons should not be exposed. The second incision is along the medial aspect of the leg approximately 2 cm posterior to the edge of the tibia. The incision is tailored to avoid injury to the saphenous vein and accompanying saphenous nerve. The fascia overlying the gastrocnemius and soleus muscles is divided, thereby opening the superficial posterior compartment. Using electrocautery, the deep posterior compartment is decompressed by detaching the insertion of the soleus muscle from the tibia, with care to protect the posterior tibial neurovascular bundle. This maneuver exposes the fascia overlying the flexor digitorum longus, which is divided along the length of the muscle, completing full release of this vital compartment. Once the posterior aspect of the tibia is visualized directly, one knows that the deep posterior compartment has been fully decompressed.

THE THIGH AND BUTTOCKS

The thigh has three compartments: the anterior, medial, and posterior. Most thigh compartment syndromes involve the anterior and posterior compartments, each of which has a major nerve coursing through it. Relevant structures within the anterior compartment include the femoral vessels, the femoral nerve, and the lateral cutaneous nerve. The posterior compartment contains the sciatic nerve. The medial compartment has no major neurologic structure within it and does not usually require decompression. Most thigh compartment syndromes are the result of femur fractures or arterial injuries.^{22,23} The gluteal muscle group of the buttocks is enclosed by the fascia lata, defining another compartment vulnerable to increased pressures and involvement of the sciatic nerve, as well as the muscles themselves.²⁴

Decompression of the anterior and posterior thigh compartments is readily accomplished using a full-length lateral

thigh incision extending from the intertrochanteric line down to the lateral femoral epicondyle [see Figure 3]. The anterior compartment is opened by incising the underlying fascia lata. The posterior compartment is decompressed by retracting the vastus lateralis muscle medially to expose the lateral intermuscular septum, which is then opened the length of the incision. Following decompression of the anterior and posterior compartments, a pressure measurement of the medial compartment may be obtained. If necessary, the medial compartment is decompressed with the same medial incision used to expose the superficial femoral artery beneath the sartorius muscle; subcutaneous extension of this approach across the anterior surface of the thigh will also allow decompression of the anterior compartment.²² Decompression of the gluteal musculature of the buttocks is performed using longitudinal incisions through the skin with individual epimysial envelope incisions as needed.⁴

THE FOREARM

The forearm is wrapped in a firm layer of deep fascia that is continuous with the deep fascia of the arm. In addition, there are septa running from the deep fascia to the radius and ulna. Finally, a dense interosseous membrane connects the radius and ulna. This compartmentalization results in three forearm compartments: the volar, dorsal, and mobile wad. Although some authorities further subdivide the volar compartment into a superficial volar and a deep compartment, most reports and technique descriptions focus on the notion of three forearm compartments.²⁵ The two major compartments, volar and dorsal, are divided by the thick interosseous membrane that connects the radius and ulna. The third compartment, the mobile wad compartment, runs along the lateral (radial) aspect of the forearm.

The volar compartment contains the flexor musculature, along with the median and ulnar nerves, which innervate the flexors. The median nerve is most frequently involved in a compartment syndrome of the forearm because it pursues a deeper, more vulnerable course than the ulnar nerve. The radial and ulnar arteries also course through the volar compartment. The dorsal compartment contains the extensor musculature, along with the deep branch of the radial nerve (the posterior interosseous nerve), but no major arteries.²⁶ The mobile wad compartment contains the brachioradialis, extensor carpi radialis brevis, and extensor carpi radialis longus muscles; these muscles are anatomically transitional between the volar and dorsal muscle groups but are properly associated with the extensor group because of their innervation by the superficial branch of the radial nerve. The forearm muscles that are at increased risk for ischemic injury are in the volar compartment, especially the flexor pollicis longus and the flexor digitorum longus, which run deep and lie directly anterior to the unyielding interosseous membrane that connects the radius and ulna; thus, the upper extremity compartment most often requiring decompression is the volar compartment of the forearm.

A wide variety of both blunt and penetrating traumatic mechanisms can lead to the development of a compartment syndrome in the upper extremity.²⁷ The diagnosis should be suspected in children following supracondylar fracture of the humerus, the mechanism of injury leading to the original description of ischemic contracture of the forearm by

Figure 3 Fasciotomy of the thigh. (a) Skin incision for thigh fasciotomy at the lateral aspect of the leg, along the femur, which allows decompression of the lateral and posterior compartments. (b) Midthigh cross-sectional view of the decompression of the lateral, medial, and posterior compartments of the thigh through two incisions.

Volkmann in 1881.¹ Other clinical situations possibly leading to a forearm compartment syndrome include high-energy injuries with fractures of the forearm, iatrogenic or traumatic arterial injury, subfascial intravenous fluid infiltration, crush injury, and reimplantation of the hand or forearm.^{4,25}

Timely surgical intervention with fasciotomy is the mainstay of treatment. Complete fasciotomy of the forearm is performed using volar and dorsal incisions. However, most forearm compartment syndromes are successfully decompressed with a volar incision only. Two incisions are available

to decompress the volar compartments; one courses along the lateral (radial) aspect of the forearm and the other along the medial (ulnar) side. Each works quite well, and the choice may be based on the pattern of injury and the need for possible soft tissue coverage of an associated orthopedic or vascular repair.

The first approach employs a laterally based (radial) incision for fasciotomy of the volar compartment [see Figure 4a]. This allows exposure of the brachial artery and ready decompression of the mobile wad compartment if needed;

Figure 4 Fasciotomy of the forearm. (a) The preferred volar incision, through which the volar and mobile wad compartments may be decompressed. (b) A variant of the volar incision that may be used in the setting of radial artery reconstruction or radius external fixator placement. This incision allows decompression of the mobile wad and volar compartments. (c) Dorsal incision for decompression of the dorsal forearm compartment.

consequently, release of any pressure on the radial nerve is accomplished through this approach. This volar incision should extend from the distal arm down to the carpal tunnel. The incision is begun medially just proximal to the antecubital crease and has an S-shaped configuration that begins medial to the biceps tendon and extends across the antecubital fossa down the lateral (radial) aspect of the forearm. It continues distally along the medial border of the brachioradialis muscle, continuing across the palm along the thenar crease. The fascia overlying the superficial flexor compartment is released, beginning 1 to 2 cm proximal to the elbow and extending distally across the carpal tunnel onto the palm. The incision may be extended across the wrist out onto the hand to divide the transcarpal ligament to decompress the carpal tunnel as needed. This maneuver decompresses the median, ulnar, and radial nerves, as well as the flexor/pronator musculature and the extrinsic muscles of the fingers and thumb. Proximally at the antecubital fossa, the lacertus fibrosus should be divided to release pressure on the median nerve. The resultant skin flap is designed to maintain soft tissue coverage of the median nerve and the flexor tendons. If possible, the skin overlying the carpal tunnel may be loosely approximated to prevent exposure and desiccation of the flexor tendons. Intraoperative measurement of the deep muscle compartment pressure will guide this decision.

An alternative approach uses a curvilinear medially based (ulnar) volar incision, which allows release of the flexor muscle compartment [see Figure 4b]. The course of the incision may be tailored to accommodate preexisting traumatic wounds and tissue loss.⁴ In severe cases, the deep intramuscular fascia enveloping the flexor digitorum superficialis, the flexor digitorum profundus, and the flexor pollicis longus may also require decompression.⁴

The need for the additional dorsal fasciotomy incision may be determined by intraoperative pressure measurements of the dorsal compartment following release of the volar compartment. A longitudinal incision along the posterior aspect of the forearm releases the dorsal compartment and its extensor musculature. This linear incision extends from the lateral epicondyle down to the midline of the wrist. The interval between the extensor carpi ulnaris and the extensor digitorum communis is identified; the fascia between these two muscle groups is then divided [see Figure 4c]. Postoperatively, the open incisions are loosely dressed with moist saline gauze and the limb is maintained in a functional position.

THE ARM

The arm has two compartments: anterior and posterior. The anterior compartment contains the brachial vessels along with the median, ulnar, and musculocutaneous nerves. The radial nerve runs through the posterior compartment. The fascia encompassing the compartments of the arm is not as rigid and unyielding as that of the leg. As a result, compartment syndromes of the arm are not common and may be difficult to recognize. They most often occur in conjunction with injuries causing a compartment syndrome of the forearm.²⁸ Both compartments of the arm may be decompressed through a single incision along the lateral border of the biceps muscle. This incision releases the anterior compartment. If the posterior compartment requires decompression, it is opened by dividing the intermuscular septum of the arm deep to the biceps muscle. For more extensive injuries with severe swelling, fasciotomy of the arm may be performed using the two incisions depicted in Figure 5.

Postoperative Care and Wound Closure

Discussion regarding fasciotomy is usually focused on its appropriate indications and proper technique. Although less exciting and dramatic than the urgent fasciotomy procedure, its aftermath is equally important. The postoperative care and closure of the wound should not be overlooked. The patient may require support for rhabdomyolysis, myoglobinuria, and renal failure in the acute postoperative phase. Once the patient is clinically stabilized and the acute illness or injury has been overcome, the challenge of closing a large soft tissue defect must be addressed [see Figure 6].

The most commonly described technique of delayed primary closure is the shoelace technique. Sterile rubber bands, or vessel loops, can be placed at the time of fasciotomy in a criss-crossing, shoelace pattern using skin staples for anchors. The vessel loops are stapled to the wound edges of the fasciotomy. The bands are gradually tightened daily as the swelling decreases [see Figure 7]. It is essential to note that the closure process should not be initiated until the acute compartment syndrome has resolved. This method usually results

SCORE

in delayed primary wound closure with very acceptable cosmetic and functional outcomes.

Traditionally, wounds have been managed with moist dressings until they are eventually covered with skin grafts or closed primarily. A newer wound management strategy is the Wound Vac device, which employs negative pressure wound therapy (V.A.C. System, KCI Medical, San Antonio, TX); this method is used in place of standard moist gauze dressings, with reports of a higher rate of primary closure²⁹ [see Figure 8]. For final closure of the wound, several techniques of delayed primary closure have been described for improvement of cosmetic outcome and ease of closure [see Figure 9].

Other innovations have been developed to achieve the same goal of delayed primary closure. The concept of dermatotraction uses the elastic properties of skin to maximize primary closure of a fasciotomy wound. Recently, a new device using stainless steel skin anchors and a nylon line provides an elegant means of applying a defined, calibrated degree of traction to reapproximate the wound margins; an integral clutch mechanism provides a continuous controlled dynamic pulling force (Dermaclose, Wound Care Technologies, Inc., Chanhassen, MN).

The rubber band/vessel loop shoelace technique is probably the most simple and effective method for closure of most fasciotomy wound skin defects. However, the method

of closure must be individualized based on patient compliance, equipment availability, cost, and wound factors such as tension and amount of myonecrosis. It is important that the surgeon be familiar with the various closure techniques so that the particular method used optimizes the functional outcome of the fasciotomy procedure for that individual patient.

Chronic Exertional Compartment Syndrome

CECS is a well-recognized entity that tends to occur in relatively young athletes. CECSs arise from repetitive exertion and exercise. Vigorous exercise can increase muscle volume by 20%, causing an increase in pressure within the fixed compartment. Chronically recurring increased pressure within the closed space can cause debilitating symptoms in the athlete; this is most often seen in long-distance runners

Figure 8 Photograph of vacuum dressing for a fasciotomy wound.

and military recruits and usually involves the anterior or deep posterior compartment of the leg.² Weight lifters may also develop this chronic disorder, especially in the forearm.³

Potential causes of CECS include hypertrophy from aggressive training, altered fascial compliance, and myofascial scarring associated with repetitive impact stress and inflammation.² Involvement of the leg is more common, typically affecting runners and soccer players. CECS of the forearm is less common and is seen in competitive motorcyclists,³⁰ weight lifters, and manual laborers. Previous orthopedic trauma is common for both locations. In both sites, diagnosis is based on symptoms and measurement of compartment pressures.

THE FOREARM

Typical symptoms suggestive of CECS of the forearm include forearm pain with exertion that disappears with rest.

Figure 7 Photograph of leg fasciotomy wound approximation using the shoelace technique.

Figure 9 Photograph of delayed primary closure of fasciotomy wounds after vacuum dressing therapy.

Paresthesias are often felt in the fingers. Transient hand dysfunction or cramping has also been described. Examination at the time of symptoms usually reveals a firm, stiff compartment. Diagnosis is confirmed by direct dynamic measurement of compartment pressures using the Stryker STIC device. Measurements are obtained with the patient at rest, during exertion, and following the exercise stress. A finding of a compartment pressure greater than 30 mm Hg in any compartment is abnormal. No further studies are required.³⁰ Treatment requires complete release of involved compartments. Release of the forearm compartments may be performed as an outpatient procedure using a tourniquet under general anesthesia. Release of the compartments is performed using either two volar incisions or two dorsal incisions depending on the compartments involved. Details of the surgical technique are outlined in Croutzet and colleagues' study.³⁰ Sutures are removed at 2 weeks, with initiation of normal daily activities and an exercise program. Full exertional activity is typically reached at 6 weeks following operation.³⁰

THE LEG

CECS involving the leg typically results in atypical claudication symptoms characterized by isolated muscle cramping or swelling with occasional paresthesias localized to the dorsal or plantar surface of the foot. The onset of symptoms is fixed and reproducible but usually occurs at a very long exercise distance, often measured in miles rather than city blocks. Although symptoms may abate with rest, they quickly return with resumption of exertion. These symptoms rarely respond to nonsteroidal antiinflammatory drugs (NSAIDs) or physical therapy. A consistent pattern of failed medical management is characteristic.

Initially noted to be more common in men, the gender profile has shifted dramatically over the past 20 years. Women now comprise more than 70% of patients in Turnipseed's comprehensive analysis of 28 years of experience.² Initially more common in runners, the most common sport associated with CECS of the leg is now soccer. The average age of patients is 32 years. Symptoms are unilateral in 44% of patients.

The most commonly affected lower extremity muscle groups are in the anterolateral (72%), deep posterior (16%), and superficial posterior (12%) compartments. Plantar foot paresthesia is most commonly associated with the deep posterior compartment; dorsal foot paresthesia results from involvement of the anterolateral compartments. Diagnosis is confirmed by measurement of compartment pressures at rest and following exercise. Normal resting pressure within the leg compartments is less than 15 mm Hg. Resting pressures ranging from 16 to 24 mm Hg are suggestive of CECS, whereas pressures greater than 25 mm Hg are considered diagnostic. Those patients with borderline resting compartment pressures (16 to 24 mm Hg) are retested following exercise stress. Postexercise compartment pressure usually returns to baseline within 3 minutes. If the compartment pressure remains elevated (> 25 mm Hg) for more than 10 minutes after exercise, this is considered a positive provocative stress test result.²

Initial treatment of CECS of the leg may include rest, along with modification of the intensity and duration of

workouts; however, most high-level athletes are not willing or are unable to adjust their training schedules as a permanent means of controlling symptoms. Failure to respond to nonsurgical treatment or the inability to pursue a non-invasive treatment regimen leads to the need for surgical intervention.

The surgical approach to CECS involves either a fasciotomy or fasciectomy procedure. Whereas fasciotomy is probably a more common procedure, fasciectomy with open technique seems to yield more durable positive results with fewer complications. As described by Turnipseed, the open procedure is performed through a 2.5 to 3.0 cm incision, an ellipse of the fascia encasing the involved compartments is excised, and then, under direct vision, the fascia can be released from the level of the tibial plateau down to about 2 cm above the ankle level.² The small incisions (< 3 cm) required for this approach yield acceptable cosmetic outcomes with fewer postoperative complications than semi-closed methods with limited incisions and exposure. Either method can be performed in the ambulatory setting using local anesthesia with intravenous sedation. Structured rehabilitation programs allow a graduated return to full activity over 3 months.

Abdominal Compartment Syndrome

The physiology of abdominal compartment syndrome is consistent with that of extremity compartment syndrome in that increased pressure in a rigid volume causes tissue ischemia. Abdominal compartment syndrome can occur postoperatively after abdominal operations (e.g., tight closure after abdominal wall herniorrhaphy, aortic cross-clamping), and secondary abdominal compartment syndrome can result from massive fluid resuscitation. The signs and symptoms of abdominal compartment syndrome differ from those of extremity compartment syndrome because of the contents of the abdominal compartment. Compression of the inferior vena cava results in diminished preload and decreased cardiac output, which may cause hypotension. Decreased venous return of intra-abdominal organs contributes further to organ ischemia, resulting in bowel necrosis and hepatic ischemia. The compliance of the thoracic cavity is decreased, resulting in hypoventilation as a result of the inability to expand the thoracic cavity and elevation in airway pressure. Intra-abdominal hypertension also results in compression of kidneys, resulting in oliguria attributable to mechanisms not yet defined.

In contrast to extremity compartment syndrome, abdominal compartment syndrome is very difficult to diagnose by physical examination. Manometry for the diagnosis of abdominal compartment syndrome should be performed and can be accomplished by the measurement of bladder pressure. Twenty-five milliliters of normal saline solution is instilled in the bladder via a Foley catheter. The catheter is connected to a transducer device, which should be positioned at the level of the midaxillary line. The pressure is measured at end-expiration. For accuracy, multiple measurements are taken. Normal intra-abdominal pressure (IAP) is 5 to 7 mm Hg. Intra-abdominal hypertension is defined as IAP greater than 11 mm Hg.³¹ Abdominal perfusion pressure can also be measured by subtracting the IAP from the systemic mean arterial

pressure. However, the diagnostic value of this has not been confirmed by prospective studies. Therefore, the current standard of diagnosis is the IAP. The grading system instated by the World Congress on Abdominal Compartment Syndrome is as follows: grade I, IAP 12 to 15 mm Hg; grade II, IAP 16 to 20 mm Hg; grade III, IAP 21 to 25 mm Hg; and grade IV, IAP > 25 mm Hg. Those patients in grades I and II can be managed medically with gastric decompression, sedation, diuresis or ultrafiltration. Patients falling within grade III should be clinically evaluated for signs of end-organ failure. If those signs are present, decompressive laparotomy is indicated. For grade III patients without evidence of organ failure, close monitoring is essential. Neuromuscular blockade for relaxation of the abdominal wall musculature may

decrease IAP. For those patients in grade IV, decompressive laparotomy is usually necessary. Failure of medical therapy and signs of end-organ ischemia mandate decompression. For those patients with intra-abdominal fluid, blood, or abscess causing compartment syndrome, catheter drainage is acceptable.³²

After laparotomy for decompression, temporary abdominal closure can be achieved with either a Bogota bag sutured to the skin or a vacuum-assisted device for closure. Primary closure is usually possible within 5 to 7 days of decompression. After closure, the patient must be monitored for recurrent abdominal compartment syndrome.

32 CURRENT MODALITIES FOR IMAGING THE VASCULAR SYSTEM

Aoife N. Keeling, FFRRCSI, and Peter A. Naughton, MD

Over the last two decades, there has been a paradigm shift for both the diagnosis and the treatment of many vascular pathologies. Noninvasive imaging using duplex ultrasonography (US), computed tomography (CT), and magnetic resonance angiography (MRA) is now often preferred to digital subtraction angiography (DSA) for diagnosis, and endovascular intervention has emerged as an attractive alternative to open surgery for the treatment of many vascular conditions. This chapter focuses on the noninvasive imaging modalities currently used in the investigation and diagnosis of both arterial and venous disorders, covering both technical factors and clinical applications with a number of case-based examples.

Plain Film

Previously, prior to the widespread use of computed tomographic angiography (CTA) and MRA, plain film could be used to assist in the diagnosis of certain vascular pathologies, including aneurysmal disease, atherosclerosis, trauma, and postoperative follow-up. Now with the many other imaging modalities available, the emphasis has moved away from plain film radiography. However, vascular specialists should be aware of their current role in vascular diagnosis, often incidentally, and in postprocedural follow-up.

Aneurysms, particularly abdominal aortic aneurysms (AAAs), can be diagnosed incidentally on an abdominal radiograph manifested by the presence of retroperitoneal linear calcification representing the calcified atherosclerotic aortic wall. Similarly, mesenteric arterial aneurysms can also be identified as concentric or curvilinear calcification within the right or left upper quadrant. This finding should prompt further investigation with US or CTA. Thoracic aortic aneurysms and pseudoaneurysms may also be incidentally diagnosed on chest radiographs, usually manifesting as a widened mediastinum. Ascending thoracic aortic aneurysms/pseudoaneurysms can produce a right sided mediastinal mass on CXR, with descending thoracic aortic aneurysms/pseudoaneurysms causing a left sided mediastinal mass. Linear calcification along the aneurysmal aortic wall or within the rim of a pseudoaneurysm can be identified on CXR. CXR may also reveal mass effect from the aneurysms/pseudoaneurysms, manifested by downward displacement of the left mainstem bronchus. Similarly, unrecognized thoracic aortic coarctations can present incidentally on a chest x-ray in teenagers or young adults with the classical rib notching and small mediastinum [see *Figure 1*].

Prior to the widespread use and availability of CTA in the emergency setting, a small study demonstrated that the diagnosis of an AAA contained rupture could be made in a

large proportion (90%) of patients on the basis of plain abdominal radiograph findings.¹ Plain film findings including the presence of aortic rim calcification (65%), soft tissue mass (67%), loss of psoas muscle (75%) or renal (78%) outlines, renal displacement (25%), and properitoneal flank stripe changes (19%) were all associated with an AAA rupture in the correct clinical context.¹ Acute thoracic aortic injury including transection has a number of classical findings on plain chest radiograph, including signs of mediastinal hematoma—widened mediastinum, deviation of the trachea to the right of the T4 spinous process, deviation of a nasogastric tube to the right of the T4 spinous process, obscuration of the margin of the aortic arch, left apical cap, depression of the left mainstem bronchus, and loss of the aortopulmonary window—and associated signs, including fractured first and/or second rib, left pleural effusion from hemothorax, and left pneumothorax or hemopneumothorax. However, these plain film findings are not specific; thus, CTA is required for definitive diagnosis and preprocedural planning.²

Figure 1 A 21-year-old female with a cough and fever underwent a chest radiograph to evaluate for pneumonia. Incidental note was made of bilateral rib notching (arrows). This was confirmed at time-resolved magnetic resonance angiography to be an aortic coarctation with multiple arterial collaterals resulting in the bilateral rib notching.

Plain film acquisition has been advocated in the annual follow-up of endovascular aneurysm repair (EVAR) of both thoracic and abdominal aortic aneurysms to detect late stent graft-related complications.³ Type III endoleaks can occur from a device-related complication attributable to migration and separation of the iliac extension limbs from the stent graft main body. Plain film can identify limb separation and may be an adequate sole imaging modality to detect this potential complication.⁴ Also, stent grafts, mainly the unsupported devices, can kink, fracture, and infold, all of which can be detected on plain radiographs. Kinking and infolding may lead to stent graft occlusion. Infolding is reported with the earlier Gore TAG thoracic stent graft devices (W.L. Gore & Associates, Flagstaff, AZ) in cases of acute thoracic aortic transection in young patients with normal-size aortas. This infolding is most likely attributable to oversizing of the device.⁵ Plain films can accurately demonstrate this stent graft infolding, as Leung and colleagues have illustrated.⁵

Another endovascular procedure that some authors advocate for imaging follow-up is that of vena caval filter insertion. At present, two filter classes are available on the market, optional or retrievable and permanent, both serving to prevent large pulmonary emboli but for differing clinical scenarios. Optional or retrievable caval filters allow for removal of the caval filter when the risk of pulmonary embolus is removed or when appropriate anticoagulation therapy can be commenced. However, permanent caval filters remain within the cava for the remainder of the patient's life, and some authors advocate imaging follow-up to detect any device-related complications, including fracture, migration, embolization, or caval thrombosis. Greenfield and Rutherford asserted that following filter insertion, a plain abdominal x-ray should be acquired the next day, then every 6 months for 2 years, and then yearly to ensure adequate filter position⁶ [see Figure 2]. Doppler US of the cava was also recommended at 3 months, then every 6 months for 2 years, and then yearly to ensure patency.

Ultrasonography

Duplex US, combining real-time B-mode information and flow characteristics from pulsed-wave Doppler US, has been the first-line investigation for vascular imaging for many years. The main benefits of duplex US are that it is cheap; it provides important hemodynamic, physiologic and anatomic information; it has no ionizing radiation; it is a portable, reproducible, real-time technique; and it can guide arterial and venous interventions. The limitations are that it is operator dependent, patient dependent (it performs poorly in obese patients), and anatomic location dependent (it performs poorly in deep locations such as the pelvis or thorax); it is inhibited by overlying bowel gas, bone, or lung and by arterial wall calcification; and it is time consuming to image the entire peripheral arterial tree.

PERIPHERAL ARTERIAL DISEASE

Various measurements are attained in the vascular laboratory to assess and evaluate for critical arterial stenosis. Measurement of pressure and flow is the cornerstone of assessing for peripheral arterial disease (PAD). Frequently performed pressure assessments include the ankle-brachial index (ABI)

Figure 2 A 65-year-old female following intracranial aneurysmal clipping developed a pulmonary embolus but was unable to receive anticoagulation because of the recent intracranial surgery. Thus, a retrievable caval filter was placed. A plain film following filter insertion demonstrates a retrievable Cook Celect filter (Cook Medical, Bloomington, IN) within the infrarenal cava without any tilt (arrow).

and segmental and toe pressures. Drops in pressure correlate to luminal stenosis; for example, a normal ABI is 1.11 ± 0.1 ; for patients with intermittent claudication, the ABI is 0.59 ± 0.15 ; and patients with rest pain have a characteristic ABI of 0.26 ± 0.13 .⁷

Flow characteristics including peak systolic and end-diastolic velocity, pulse contour, and amplitude (waveform) may be determined using duplex US and plethysmography. Waveforms are useful in identifying a proximal occlusive stenosis. Mazzariol and colleagues reported that a severely abnormal common femoral artery waveform was 100% predictive for detecting iliac artery stenosis greater than 50%.⁸ Mildly abnormal common femoral artery waveforms unfortunately did not exclude significant proximal stenosis; therefore, additional imaging modalities were required. Mazzariol and colleagues concluded that duplex US was able to provide enough information for surgery in more than 83% of patients.⁸ For infrainguinal disease, a significant stenosis is defined as a twofold or greater increase in peak systolic velocity (PSV) or the absence of blood flow consistent with an occlusion. In similar studies, Proai and colleagues and Grassbaugh and colleagues reported that duplex US was predictive in 88% of patients compared with 93% of patients undergoing conventional angiography.^{9,10} Despite the fact that TASC II¹¹ does not recommend bypass graft surveillance with US, it is widely used for peripheral bypass graft surveillance, and many authors attest to its value¹² [see Figure 3].

A recent meta-analysis evaluated the diagnostic accuracy of MRA (time of flight [TOF]), contrast enhanced CTA, and duplex US for diagnosing arterial stenoses equal to or greater than 50% and arterial occlusions within the lower limb.¹³

Figure 3 A 68-year-old female presented with two-block intermittent claudication, no rest pain, and no ulceration. A right femoropopliteal vein bypass was created 6 years previously. (a) A duplex sonogram of the vein bypass demonstrates a tight stenosis within the midvein bypass with markedly elevated peak systolic velocity (PSV) of 260 cm/s. (b) A duplex sonogram of the vein bypass distal to the stenosis demonstrates patency but a dampened waveform with a PSV of 20 cm/s.

Duplex US had a median sensitivity and specificity of 88% (80 to 98%) and 96% (89 to 99%), respectively, for lesions at all sites; 88% and 95%, respectively, for lesions above the knee; and 84% and 93%, respectively, for lesions below the knee.¹³ Another meta-analysis also demonstrated a lower sensitivity and specificity for duplex US compared with MRA as the authors concluded that the sensitivity for MRA was 97.5% compared with 87.6% for duplex US.¹⁴ The specificity of the two tests was similar, 96.2% versus 94.7%.¹⁴

DUPLEX US FOR AAA

Sixty percent of AAAs are asymptomatic and are diagnosed incidentally on physical examination or imaging. US is advocated as the imaging modality of choice for AAA screening.^{15,16} A sonographic diagnosis of an AAA is achieved when the diameter of the dilated segment of aorta is 1.5 times greater than the adjacent unaffected aorta. Ultrasound interrogation of an AAA involves taking longitudinal, transverse, and coronal views [see Figure 4a]. However, US has several shortcomings, including variability in transverse dimensions of the aneurysm sac, limitations in aneurysm neck assessment, and limited visualization of luminal thrombus.¹⁷ The Society for Vascular Surgery has launched a national program to screen large populations for carotid artery stenosis, AAAs, and PAD. The screening program consists of a truncated carotid artery scan, an abdominal ultrasound to detect AAAs, and an ABI. Flinn reported the finding of unsuspected aneurysms in 2.2% of patients, carotid stenosis greater than 50% in 7.6% of patients, and PAD in 7% patients.¹⁸

US is also important in the postoperative surveillance of patients. Endoleak is defined as the persistence of blood flow within the aortic sac following stent graft deployment. Despite continued improvement in stent graft design, the occurrence of endoleaks remains the Achilles heel of EVAR. Posttreatment surveillance is therefore necessary to detect endoleaks and identify the patients who may require reintervention.

Initially, CT was solely employed for this surveillance; however, many centers, in an effort to minimize patient radiation exposure, are now advocating the role of colour duplex US, either alone or in combination with plain films. Color Doppler examination in a patient following EVAR enables one to determine the presence of endoleak, identify the source of endoleak, measure maximum sac diameter, and assess the flow within the stent graft [see Figure 4, b and c].

Aortic duplex US can aid in the diagnosis of other aortic pathologies as well as aneurysmal disease, such as atherosclerosis causing stenoses, dissection with the characteristic finding of an intimal flap [see Figure 5], arteriovenous fistulae (AVF), and pseudoaneurysms.

DUPLEX US FOR CAROTID ARTERY STENOSIS

Patients with severe symptomatic carotid artery stenosis are at high risk for ipsilateral ischemic stroke; thus, appropriate intervention, surgical or endovascular, is vital to prevent disabling stroke. The North American Symptomatic Carotid Endarterectomy Trial (NASCET)¹⁹ and the European Carotid Surgery Trial (ECST)²⁰ measured the degree of internal carotid artery (ICA) stenosis with intra-arterial angiography and then determined if carotid endarterectomy (CEA) had a benefit in reducing the stroke rate in the less than 50%, 50 to 69%, and 70% or more ICA stenosis groups. The NASCET concluded that there was a sustained benefit in treating patients with CEA with 50% or greater symptomatic stenosis.¹⁹ Although DSA remains the gold standard, diagnostic DSA has a 1% risk of stroke and a less than 1% risk of death; thus, noninvasive imaging with duplex US, CTA, and MRA is now widely practiced, and DSA is usually reserved for indeterminate cases or prior to carotid arterial stenting.

Duplex US enables one to evaluate waveforms at the common carotid artery, prestenotic ICA, stenosis of ICA, and poststenotic ICA [see Figure 6]. Langlois and colleagues first correlated PSV and end-diastolic velocity, measured by duplex US, compared with the degree of ICA stenosis

Figure 4 A 59-year-old male smoker underwent aneurysm screening ultrasonography. (a) A longitudinal view demonstrates a 5.5 cm infrarenal abdominal aortic aneurysm with thrombus (star) within the sac. (b) Ultrasonography was used for follow-up post-endovascular aneurysm repair. Note the stent graft (arrow) excluding the aneurysmal sac with an overall reduction in sac size compared with the initial sonogram. (c) A color duplex sonogram demonstrates patency of the main body of the stent graft (arrow) and the contralateral iliac limb (curved arrow). No endoleak was identified on this surveillance duplex ultrasound examination.

Figure 5 A 67-year-old male with sudden-onset back pain underwent duplex ultrasonography. The initial sonogram demonstrated a flap within the lumen of the abdominal aorta consistent with a dissection flap (arrow).

determined by DSA.²¹ Following the NASCET and the ECST, this correlation has subsequently been revised by the Society of Radiologists in Ultrasound Consensus Committee.²² Each vascular laboratory needs to develop its own internally validated criteria. Duplex US assessment of ICA stenosis using the consensus and internally validated criteria also obviates the confusion that occurs when assessing stenosis angiographically as three different methods are commonly used (the NASCET, ECST, and common carotid artery methods). These different methods and calculations explain the differences found between the NASCET and the ECST; for example, a 50% ICA stenosis determined by the NASCET method correlates to a 75% ICA stenosis by the ECST method.

In addition to calculating ICA stenosis, duplex US also provides important information regarding plaque characterization: ulcerated versus nonulcerated surface, hypoechoic (fibrofatty) versus echogenic (calcified), stability of the overlying cap, and homogeneous versus heterogeneous plaque. The external carotid artery and proximal vertebral and subclavian arteries are also visualized when completing the duplex US. Diagnosis and assessment of nonatheromatous conditions including carotid dissection, carotid body tumor, carotid artery kinks, and fibromuscular dysplasia may be elicited using duplex US.

Duplex US may be limited in differentiating near and complete occlusion, investigating heavily calcified lesions, and evaluating for in-stent restenosis.

DUPLEX US FOR RENAL AND MESENTERIC DISEASE

Color and pulsed Doppler evaluation of splenic and renal vessels can be used to evaluate for chronic mesenteric ischemia or renal artery stenosis (RAS). Examination may be limited by patient obesity or operator experience. The technique used to complete the evaluation of these vessels is beyond the scope of this chapter, but in brief, patients are best examined early in the morning after overnight fasting to minimize scatter and attenuation by intra-abdominal bowel gas and

Figure 6 A 69-year-old male with a history of two transient ischemic attacks presented for investigation. (a) Duplex ultrasonography of both carotid arteries was performed. The longitudinal B-mode ultrasound demonstrates an eccentric echogenic plaque (arrow) within the right internal carotid artery (ICA) causing a marked stenosis. There is no evidence of shadowing and thus no significant calcification. Thus, this is consistent with a soft, lipid-rich plaque. (b) When the color Doppler is placed over the stenosis, there is marked luminal compromise (arrow). The peak systolic velocity is 429 cm/s. These findings are consistent with a significant greater than 70% stenosis. This patient went on to digital subtraction angiography and was treated with a carotid stent.

are examined in the supine and lateral positions using a low-frequency (2 to 5 MHz) transducer. The vessels are located by identifying and following the abdominal aorta. Blood flow velocity, particularly PSV, and a ratio of mesenteric vessel PSV to aortic PSV are calculated. Moneta and colleagues

compared velocities to angiograms in 34 patients with mesenteric stenosis and found that a PSV greater than 200 cm/s in the celiac artery and greater than 275 cm/s in the superior mesenteric artery (SMA) was predictive of a greater than 70% stenosis on an angiogram.²³ A mesenteric-aortic ratio greater than 3 indicates a hemodynamically significant stenosis. A PSV greater than 180 cm/s correlates to significant RAS, and a renal:aortic velocity ratio greater than 3.5 conforms to a greater than 60% RAS.

DUPLEX US FOR VENOUS DISEASE

Lower limb venous disease most commonly involves venous thromboembolism (VTE) and chronic venous insufficiency, with up to one in 20 people being diagnosed with VTE over the course of a lifetime.^{24–26} US forms the mainstay of diagnosis for both of these venous conditions. Normal lower extremity veins have characteristic findings on duplex US, including thin, nonechogenic walls, normal valves, and compressibility; the diameter is usually larger than that of the corresponding artery, and the diameter of the large veins changes with respiration (increases with deep inspiration or Valsalva maneuver). Blood flow within medium to large veins is described as spontaneous (occurs without extrinsic compression), phasic (changes in response to respiration, that is, flow cessation with Valsalva maneuver), augmented (increases in flow with manual compression of the limb distal to the ultrasound probe), and unidirectional [see Figure 7].

Venous thrombus originates focally within the vein and then begins to propagate along the vein. In the acute phase, an acute inflammatory response is initiated and typically lasts 7 to 14 days. Thrombus in the acute phase is loosely attached to the vein wall and subsequently is at the highest risk of embolization. Several key characteristic findings on US in acute thrombosis include low thrombus echogenicity identified by a flow void and lack of vein compressibility, venous distention, loss of compressibility, free-floating thrombus, diminished or absent flow augmentation, and phasisty and venous collateralization [see Figure 8]. It is clinically important to diagnose an acute thrombosis to prevent thrombus propagation and embolization and potentially limit the

Figure 7 An ultrasound demonstrating a normal venous flow pattern within the popliteal vein.

Figure 8 A 46-year-old male presented with left lower limb swelling and tenderness. (a) An ultrasound of the deep venous system of the left leg demonstrates echogenic material within the left superficial femoral vein (LSFV) (white star). There is noncompressibility of the LSFV (right panel). (b) On a color duplex ultrasound, there is no venous flow within the LSFV consistent with occlusive deep venous thrombus.

injurious effects of acute inflammation to veins and valves. Subacute thrombosis occurs between 2 weeks and 6 months, during which the thrombus becomes more echogenic and adherent to the vein wall and retracts, the diameter size decreases, and flow is restored. The chronic phase occurs after 6 months and is characterized by infiltration of the vein and thrombus by fibroblasts. Chronic thrombus is seen on a ultrasound as thickening and fibrosis of the vein wall, hyper-echoic calcified thrombus, valve thickening, and rigidity with reflux and lack of spontaneous, phasic, or augmented flow.

In patients with evidence of varicose veins or chronic venous insufficiency, US is used to demonstrate and locate sites of reflux in the superficial and deep venous systems. A valve reflux time greater than 0.5 seconds suggests venous insufficiency.

Within the upper extremity, venous duplex US is also valuable for the investigation of VTE, albeit performed less frequently than in the lower limb. A meta-analysis determined that upper limb duplex US had an excellent specificity (94 to 100%) but a variable sensitivity (56 to 100%) for diagnosis of arm VTE.²⁷ Venous mapping prior to hemodialysis AVF creation is performed with duplex US in many centers, with venography being reserved for problem solving. Established hemodialysis AVF can be interrogated with duplex US in the setting of poor flows, difficulty with cannulation, or prolonged bleeding following needle removal or in the dreaded situation of loss of the thrill.

Multidetector Computed Tomographic Angiography

BASIC PRINCIPLES

The basic principle of CT is to use multiple projections of an object to reconstruct the internal structure of that object

and produce a two-dimensional image. The generation of a CT image can be broken down into three stages: (1) data acquisition involving the exposure of the patient to ionizing radiation, (2) image reconstruction, and (3) image display.

DATA ACQUISITION

A CT scanner is composed of an x-ray tube, an array of detectors, and associated electronics, all mounted on a frame called a gantry. The x-ray tube produces a fan-shaped beam of x-rays that interact with the patient, some of which pass through the patient to interact with the detectors. During data acquisition, both tube and detectors rotate around the patient and the detectors repeatedly measure the number of x-rays transmitted through the patient. The amount of radiation transmitted to each detector and the gantry angle at the time of the measurement are recorded. Typically, the detector array contains 500 to 1,000 detectors, each of which is sampled approximately 1,000 times per revolution. Each line of this information reflects the summation of the attenuation coefficients (how difficult it is for an x-ray to pass through) of all structures in that x-ray path. The entire data set forms the raw data from which an image is reconstructed.

IMAGE RECONSTRUCTION

From the raw data, a digital image is created. A variety of mathematical techniques can be used to accomplish this; these rely on the principles of back-projection, iterative formulas, or analytic formulas, either with or without Fourier transformation. The result is a matrix of numbers; generally, a 512×512 matrix is employed in vascular CT. Each number in this matrix is called a pixel, and each pixel corresponds to a volume of tissue or voxel within the patient. The average density of the tissue within each voxel is represented by the

pixel value. The dimensions of the voxel in the scan plane are set by the field of view (FOV) and matrix; the dimensions of the pixel in these axes can be calculated by dividing the FOV by the matrix size. The third dimension, representing the voxel depth, is the image thickness, which is determined by the collimation width of the fan beam. The difference in attenuation of the contents of a voxel relative to water is defined as the CT attenuation number and expressed in Hounsfield units (HU). A 12-bit number scale (2^{12}) is used, which defines water as 0 and air as $-1,000$; therefore, each pixel is a number from $-1,000$ to $+3,095$.

IMAGE DISPLAY

This digital image or number matrix is converted to a visual format for interpretation. A grayscale is used, with the densest materials, such as bone (highest Hounsfield units), being assigned lighter shades (white), whereas the least dense, such as air (black) (most negative Hounsfield units), are assigned darker shades of gray. The source images are acquired and displayed in the axial plane; however, because of the large volume of data obtained with multidetector computed tomographic angiography (MDCTA), image postprocessing to enable disease interpretation is necessary. The axial image plane is no longer the only plane available for image interpretation. With multidetector computed tomography (MDCT) acquisition, near-isotropic (spatial resolution is approximately equal in all planes) data sets can be obtained and thus manipulated in all imaging planes and projections without significant loss of image quality, to enable eloquent display of the arterial anatomy and pathology. Therefore, a dedicated three-dimensional (3D) workstation to enable a real-time interactive approach to image manipulation and interpretation has now become a necessity. Available image postprocessing techniques on the clinical 3D workstations include multiplanar reconstruction, maximum-intensity projection (MIP), volume rendering, and shaded surface display.

ADVANTAGES OF MDCTA

With the advent of MDCTA, noninvasive angiography has become a viable option as a result of increased speed of acquisition, spatial resolution, and volume coverage compared with the older generation of single-detector CT scanners. Isotropic data sets can now be acquired with MDCTA, allowing for 3D reconstruction and many postprocessing methods to enable both diagnostic interpretation and eloquent anatomic and pathologic arterial display.

The alternative noninvasive imaging techniques to MDCTA are MRA and duplex US, both of which are widely used clinically. MRA has been shown to have diagnostic accuracy similar to that of MDCTA^{28,29}; however, direct comparison studies in the literature are lacking, likely attributable to the fact that each modality is usually compared with DSA for the purpose of a reference standard. Although MRA lacks the need for ionizing radiation, its major advantage over MDCTA, MRA is limited because of cost, scanner availability, local expertise, and the need for a gadolinium contrast agent, which has recently been shown to cause nephrogenic systemic fibrosis in patients with impaired renal function. Duplex US, although readily available, cheap, and safe, has a reduced

sensitivity compared with both MRA and MDCTA¹⁴ and a lower physician confidence.³⁰

LIMITATIONS OF MDCTA

CT contributes to 75% of the total collective dose from ionizing radiation to the public from medical imaging.³¹ With the increasingly widespread use of CT and individual patients having multiple scans over their lifetime, low-dose techniques are increasingly desired. The goal is to keep doses “as low as reasonably achievable” (ALARA). This represents a practice mandate adhering to the principle of keeping radiation doses to patients and personnel as low as possible. The average effective dose for peripheral arterial CTA was reported at 12.2 mGy by Catalano and colleagues,³² and a CT dose index of 12.97 mGy, with an effective dose index of 9.3 mSv, was reported by Rubin and colleagues.³³ Interestingly, the effective dose index for MDCTA of the peripheral arteries was 3.9 times lower than that for DSA, 9.3 mSv versus 36.2 mSv, respectively.³³ Of note, for comparison, a chest radiograph has an effective dose of 0.1 mSv. Low-dose techniques, involving image acquisition at a reduced milliamperage, that is, 50 mA, have been reported to be feasible and accurate when compared with DSA.³⁴ MDCTA also necessitates the intravenous administration of contrast medium, which is a potentially nephrotoxic agent; thus, care needs to be employed in administering contrast to patients with renal impairment. There is a lack of dynamic information with MDCTA in comparison with time-resolved MRA or DSA; this can even render the scan nondiagnostic if there are marked differential flow rates in the runoff arteries below the knee. An adaptive method of contrast administration described previously may prove to alleviate this issue.³⁵ Similar to most imaging techniques, patient motion will degrade MDCTA image quality and result in blurred images. A strategy to reduce this problem is to wrap a towel around the patient's lower limbs and fix them together with adhesive tape to reduce any inadvertent limb motion.³³ Image display and data storage are also limitations as vast amounts of data are acquired with each MDCTA examination. Remote access to large data sets is becoming more available with the use of “thin clients” and central servers for image processing.

ABDOMINAL AORTIC CTA

AAAs occur in up to 4% of the population above 50 years and 9% above 65 years of age. MDCTA can be used to diagnose and follow up stable aneurysms, as a tool to assist preoperative decision technique for aneurysmal repair (endovascular, open or hybrid techniques) and in the acute setting to confirm aneurysmal contained rupture. In the preoperative setting, CTA provides information on aneurysmal sac size, location, and extent; the relation of aneurysm to adjacent arterial origins; accessory arteries; and stenosis or occlusion of adjacent arteries; neck length, shape and angulation; size, tortuosity, and extent of calcification of noninvolved iliac arteries are all important characteristics that can be gleaned accurately from a CTA³⁶ [see Figure 9, a and b]. Orthogonal measurements of the aneurysm using a centerline provide accurate measurements for preprocedure planning [see Figure 9c].

Figure 9 A 68-year-old male with a pulsatile abdominal mass underwent computed tomographic angiography. (a) Coronal reconstruction from a multidetector computed tomographic angiogram (MDCTA) demonstrates an infrarenal abdominal aortic aneurysm (arrow) with thrombus within the sac and rim calcification. Note the long infrarenal neck (arrowhead). All of the necessary measurements and anatomic relations for accessing endovascular aneurysm repair (EVAR) suitability can be gleaned from the MDCTA. (b) A volume-rendered view demonstrates an overall assessment of the aortic anatomy and relation to the aneurysmal sac (arrow). Note the long infrarenal neck (arrowhead) with plenty of room for the proximal landing zone of the stent graft. The iliac arteries are slightly tortuous but are of good size and will straighten out with a stiff guide wire. (c) Many postprocessing software programs have automated programs that can provide aortic measurements; however, many interventionalists will perform their own pre-EVAR measurements.

In the acute setting in a cardiovascularly stable patient, MDCTA is the imaging modality of choice for evaluation of suspected aneurysmal rupture because of its widespread availability, speed of acquisition, temporal and spatial resolution, and excellent sensitivity and specificity.³⁷ Imaging features of an AAA rupture include initial unenhanced CT demonstrating an aneurysm with adjacent high-attenuation periaortic hemorrhage extending posterolaterally into the perirenal and

pararenal spaces of the retroperitoneum [see Figure 10]. CTA will demonstrate the aneurysm with active contrast extravasation extending outside the aneurysmal sac consistent with active arterial bleeding. A draped aorta sign occurring when the posterior wall of the aorta is indistinct from adjacent structures or closely following the contour of adjacent vertebral bodies, may be seen in a contained rupture of the posterior aortic aneurysmal wall.³⁸ Impending aneurysmal

Figure 10 An 81-year-old male presented to the emergency department with acute onset of severe back pain and an episode of collapse. (a) An axial noncontrast computed tomographic scan demonstrates a large infrarenal abdominal aortic aneurysm (star) with evidence of retroperitoneal hemorrhage (arrow). Note the high-attenuation material (arrowheads) within the thrombus of the aneurysmal sac consistent with acute hemorrhage into the thrombus-filled sac. (b) Following administration of intravenous contrast, there is evidence of jets of contrast into the thrombus within the aneurysmal sac (arrowhead) and high attenuation within the retroperitoneal hemorrhage (arrow). These findings are consistent with rupture of the infrarenal aneurysm. (c) This was successfully treated by open repair, as shown by this volume-rendered multidetector computed tomographic angiogram postrepair.

rupture in both thoracic and abdominal aneurysms may be seen as a crescent of high-attenuation contrast material within the unenhanced mural thrombus.³⁹ An aortoduodenal fistula, which may be associated with recurrent and potentially catastrophic bleeding, can be detected by loss of the normal fat plane between the aorta and duodenum and the presence of air in the aorta.⁴⁰ Currently, in the setting of a ruptured AAA, EVAR is a viable treatment option provided that favorable

aortic anatomy, adequate operator skills, endovascular facilities, and protocols are in place.⁴¹ Measurements required for calculation of the optimal dimensions of aortic stent grafts are usually obtained with MDCTA encompassing 3D reconstruction. However, in the acute rupture setting, with an unstable patient, it may sometimes be necessary to bypass MDCTA, and then on-table angiography is used to assess EVAR suitability and for stent graft size selection.⁴¹ MDCTA

can eloquently diagnose many other aortic pathologies, including dissection; atherosclerosis causing stenosis, occlusion, or ulceration; and pseudoaneurysms and mycotic aneurysms.

Patients treated with EVAR undergo frequent imaging by CTA to monitor for endoleak, stent migration or fracture, and stability of aneurysm size.⁴² An increase in the diameter of an aneurysmal sac is associated with endoleak. Evaluation of an endoleak requires an unenhanced CT scan, as well as imaging during arterial and venous phases of contrast enhancement. Unenhanced images are used to detect artifact from calcification or embolization material that may mimic endoleak on the enhanced images and to evaluate stent graft material for any infolding or migration. Arterial phase imaging enables assessment of stent graft patency and endoleak identification. Delayed venous phase images have been shown to enhance the detection rate of endoleaks as some may not be appreciated in the arterial phase.

The CT scanning volume for imaging the abdominal aorta usually starts at the diaphragm and extends caudally to the symphysis pubis. Bolus tracking triggering can reliably obtain the optimal arterial phase by placing a region of interest (ROI) on the aorta at the level of the celiac artery. An injection volume of 100 mL of high-concentration contrast agent (350 mg iodine/mL) at a flow rate of 5 mL/s is typically used. Images are acquired in the cranial to caudal direction with a slice thickness of 2.0 mm, a slice interval of 2.0 mm, and 0.6 mm of collimation.

PERIPHERAL ARTERIAL CTA

The most common indication for peripheral CTA in many centers is for further evaluation of PAD. The diagnosis has already been established clinically and with ABIs, but the extent and severity of arterial involvement are of interest to the vascular surgeon or interventional radiologist. The TransAtlantic Inter-Society Consensus (TASC) guidelines recommend appropriate endovascular or surgical treatment of PAD based on lesion location, number, severity, length, and morphology.¹¹ Peripheral CTA is well positioned to evaluate all of these criteria to enable appropriate treatment planning. MRA is also a useful modality for diagnosing the extent and severity of PAD; however, cost, scanner availability, patient contraindications, local expertise, and the risk of nephrogenic systemic fibrosis can limit this tool.⁴³ CTA can also be employed to perform bypass or vein graft surveillance⁴⁴ or follow-up of lesions treated with percutaneous transluminal angioplasty.⁴⁵ Availability and rapid access place CTA at the forefront for fast and complete arterial assessment in lower limb injury, in both trauma settings and iatrogenic events.^{46,47} Lower limb aneurysmal and pseudoaneurysmal disease can be eloquently evaluated with CTA as sac size, relation to parent vessel, thrombus load, and distal runoff can all be demonstrated prior to covered stent placement or surgical repair.⁴⁵ Rarer indications encountered include vasculitis,⁴⁷ arteriovenous malformations (AVMs),⁴⁴ and popliteal entrapment syndrome.⁴⁸

Most institutions will initially perform a scout view from the diaphragm to the feet, an optional noncontrast acquisition from the celiac axis to the feet, and an arterial phase timed acquisition from the celiac axis to the feet, with the

option of a second limited acquisition from the lower thighs to the feet in the event that the contrast has a slower transit time on the symptomatic side.

Bolus tracking triggering can reliably obtain the optimal arterial phase by placing a ROI on the aorta at the level of the celiac artery. An injection volume of 150 mL of high-concentration contrast agents (350 mg iodine/mL) at a flow rate of 5 mL/s is typically used. Images are acquired in the cranial to caudal direction with a slice thickness of 1.0 mm, a slice interval of 1.0 mm, and 0.6 mm of collimation.

CAROTID CTA

In the United States, stroke is the leading cause of adult disability and the third leading cause of death. About 80% of strokes are ischemic strokes. Conventional DSA remains the reference standard for the evaluation of carotid artery disease; however, DSA has significant risks. Thus, noninvasive methods are now widely used, usually in combination at present, with initial duplex US performed followed by cross-sectional imaging with CTA or MRA prior to intervention. There is an emerging role for CTA in the evaluation of carotid disease likely attributable to continued advances in CT technology, its noninvasive nature, and its lower cost than DSA. A recent meta-analysis assessed the accuracy of CTA versus DSA for assessment of symptomatic carotid artery disease.⁴⁹ Sensitivity and specificity for detection of a 70 to 99% carotid artery stenosis were 85% and 93%, respectively, rising to 97% and 99%, respectively, for 100% stenosis detection.⁴⁹ However, another meta-analysis comparing US, CTA, and MRA to DSA determined that contrast-enhanced MRA was the most accurate for assessing a 70 to 99% symptomatic carotid stenosis with sensitivity and specificity of 86% and 91%, respectively.⁵⁰ In this study, CTA performed poorly and was the least accurate noninvasive modality, with sensitivity and specificity for detection of 70 to 99% carotid artery stenosis of 68% and 77%, respectively, compared with 82% and 77%, respectively, for Doppler US.⁵⁰ These conflicting results from two meta-analyses should prompt further evaluation into the role of CTA in assessing carotid artery disease and should caution surgeons on the decision to proceed with intervention based solely on one noninvasive imaging modality of the carotid artery. Plaque composition can be evaluated by CTA, which is an important indicator of plaque stability and helps with the assessment of risk factors for thromboembolic events and in monitoring the effects of best medical therapy.

Other carotid pathologies can be eloquently diagnosed with CTA, including aneurysm disease [see *Figure 11*], dissection, vasculitis, and postoperative complications such as para-anastomotic aneurysms and infections. The scanning volume of carotid CTA is determined based on the initial anteroposterior and lateral topograms. The volume should include all the vascular structures from the aortic arch to the entire intracranial circulation to the level of the skull vault. This scan volume also serves to diagnose any preexisting cerebral infarcts. Automated bolus tracking or test bolus triggering techniques can reliably obtain the optimal arterial phase by placing an ROI on the aortic arch. An injection volume of 75 mL of high-concentration contrast agent (350 mg iodine/mL) at a flow rate of 5 mL/s is typically used. Images are acquired in the caudal to cranial direction with

a slice thickness of 1 mm, a slice interval of 0.5 mm, and 0.6 mm of collimation.

THORACIC CTA

The disease processes affecting the aortic root and thoracic aorta include aneurysmal dilatation and rupture, aortic dissection, intramural hematoma and penetrating ulcer, traumatic injury presenting early as transection or late as a pseudoaneurysm formation, inflammatory processes that can extend into the arch vessels, and congenital malformations. The diagnosis, surveillance, and monitoring with MDCTA play an important role in determining the timing and role for endovascular and surgical intervention.

Conventional DSA is regarded as the reference standard for evaluation of the thoracic arterial system. CTA of the thoracic aorta is currently the preferred method, however, for follow-up of patients with thoracic aortic aneurysms.⁵¹ In addition to evaluating luminal disease, CTA can also assess the vessel wall for plaque composition, hematoma, and dissections. The wall of the aneurysm is easily identified by intramural calcifications allowing for accurate size measurement. CT also allows for evaluation of the extent of mural thrombus and aneurysm wall for a contained leak, as well as any associated dissection, distal embolization, or pleural

Figure 12 A 74-year-old male undergoing computed tomography for abdominal pain. Axial multidetector computed tomographic angiography through the lower descending thoracic aorta demonstrates a small outpouching from the thoracic aorta into the aortic wall consistent with an anterior small penetrating ulcer (arrow).

Figure 13 A 40-year-old male who presented to the emergency department following a high-velocity motor vehicle accident with crushing central chest pain. An axial multidetector computed tomographic angiogram at the level of the aortic arch demonstrates increased attenuation material (*white arrow*) within the mediastinum displacing the esophagus (*arrowhead*) to the right. On the medial aspect of the undersurface of the aortic arch, at the level of the relatively fixed aortic isthmus, there is a disruption in the smooth contour of the aortic wall (*curved black arrow*), with a small area of outpouching of contrast. The finding of mediastinal hematoma (*white arrow*), along with aortic disruption in the setting of a motor vehicle accident, is consistent with acute aortic injury known as aortic transection. This requires emergent repair, with many centers now favoring endovascular and/or hybrid methods. This patient underwent a left subclavian arterial transposition. The transposition was performed before covering the transection with a stent graft to preserve the dominant left vertebral artery.

effusion. Three-dimensional images demonstrate the normal anatomic relationship of the branch vessels, the mediastinal structures, and the extent of the disease process.

MDCTA has become the imaging modality of choice for the evaluation of thoracic aortic dissection at most medical centers. Magnetic resonance imaging (MRI) and transesophageal echocardiography (TEE) are widely used with sensitivities and specificities similar to those of MDCTA; however, ease of availability, lower cost, ability to evaluate arch vessels and the abdominal aorta, increased spatial resolution, non-operator dependence, and no limited acoustic windows mean that MDCTA is preferred by many. The pathognomonic imaging finding for thoracic aortic dissection on CT is two adjacent contrast-filled lumens, which represent a patent true lumen and the false lumen. The two lumens are separated by a thin band known as the intimal flap. The intimal flap can have unusual characteristics, which are detected by CT, including partial thrombosis, a circular or spiral orientation down the aorta, or multiple fenestrations. CT is also effective for visualizing more subtle signs of dissection such as internal displacement of intimal calcium, mural thickening, ischemia of end-organs supplied by aortic branches, or a left pleural effusion. CT also demonstrates the start point, course, and extent of the intimal flap in relation to the ascending aorta, aortic arch, abdominal aorta, and branch vessel ostia, which is vital for planning surgical or endovascular repair. The major limitations of CT for thoracic aortic dissection are technical factors that can cause a false positive reading. These include improper timing of contrast bolus injection, aortic wall or cardiac motion, streak artifacts, and periaortic structures. Motion or pulsation artifact in the region of the aortic root can be misinterpreted as the flap of an aortic dissection. Aortic motion from pulsation artifact has now been virtually

Figure 14 A 63-year-old female presented with dysphagia for solids with no significant weight loss. (a) An axial multidetector computed tomographic angiogram demonstrates an artery arising from the medial aspect of the aortic arch and coursing posterior to the esophagus consistent with an aberrant right subclavian artery (*arrow*). (b) Coronal maximum-intensity projection demonstrates the aberrant right subclavian artery (*arrow*) passing posterior to the esophagus, causing posterior indentation on the esophagus. The dysphagia associated with this anatomic variant is classically known as dysphagia lusoria. This is the most common embryologic abnormality of the aortic arch, occurring in up to 1.8% of the population.

Figure 15 A 4-year-old male child with episodes of dyspnea and intermittent cyanosis and a widened mediastinum on a chest radiograph was referred for computed tomographic angiography. (a) Axial view from a multidetector computed tomographic angiogram shows a crescentic vascular ring (arrowheads) surrounding the trachea and esophagus. (b) A posterior coronal volume-rendered view demonstrates a complete vascular ring consistent with a double aortic arch with the right arch of larger caliber. The carotid arteries arise anteriorly from the common arch, and a subclavian artery arises from each of the right and left arches. This patient went on to have surgical correction because of the respiratory symptoms.

eliminated with the advent of electrocardiographic (ECG) gating and faster acquisition times, allowing for near-complete suppression of cardiac and thoracic aortic motion. ECG gating consists of image acquisition only in the diastolic phase

of the cardiac cycle when the heart, and consequently the ascending thoracic aorta, is in its most quiescent phase.

Intramural hematoma, which can also cause an acute aortic syndrome similar to dissection, may be overlooked if an initial

Figure 16 A 78-year-old male presented with acute-onset abdominal pain and one episode of diarrhea. (a) Coronal reconstruction of a noncontrast abdominal computed tomographic (CT) scan demonstrates thickened loops of small bowel (arrow). (b) An axial postcontrast T₁ fat saturation magnetic resonance image demonstrates a filling defect within the superior mesenteric vein (SMV) with expansion of the SMV (arrow) consistent with SMV thrombus, which correlates with the noncontrast CT findings.

Figure 17 A 36-year-old female presented with intermittent midline abdominal pain, weight loss, postprandial vomiting, and food avoidance. Despite her young age, symptoms were suggestive of mesenteric ischemia; thus, multidetector computed tomographic angiography (MDCTA) was performed. An axial image from the MDCTA demonstrates dilatation of the stomach (*star*) and the first and second parts of the duodenum (*x*), with a compressed third part of the duodenum (*arrowhead*) crossing the midline between the aorta and the superior mesenteric artery (SMA) (*arrow*). Note the presence of little intraperitoneal fat. The entity where the duodenum is compressed between the SMA and the aorta is known as SMA syndrome.

noncontrast scan of the thoracic aorta is not performed. This hematoma is usually attributable to bleeding of the vasa vasorum within the aortic media and results in chest pain radiating to the back, with a clinical history almost identical to dissection. The imaging features of intramural hematoma are a crescentic area of high attenuation within the aortic wall extending longitudinally and nonspirally on the noncontrast scan, which simply looks like a thickened aortic wall with a preserved lumen on the CTA. The imaging features, however, may be identical in the setting of a dissection with a small thrombosed false lumen. Also, the noncontrast images for intramural hematoma may be identical to those of a penetrating ulcer; however, the CTA will differentiate these two conditions as a penetrating ulcer appears as a contrast-filled outpouching, diverticulum-like structure penetrating into the aortic wall [see Figure 12]. Many authors regard intramural hematoma, penetrating ulcer, and aortic dissection as a spectrum of the same disease process.

CTA is now regarded as the first-line modality for evaluating traumatic disruption or transection of the thoracic aorta, replacing DSA. CTA is the cornerstone diagnostic tool because of its accessibility, noninvasiveness, rapid acquisition, and ability to evaluate the entire thorax and other body regions in a single examination.⁵² MDCTA has been shown to be nearly 100% sensitive, with, accordingly, high negative predictive value for the detection of acute thoracic injury.⁵³ CTAs can be used to plan appropriate intervention for acute thoracic transection, with many centers now advocating endovascular repair as first line treatment[see Figure 13].

Some congenital variant anatomy can be eloquently demonstrated with thoracic MDCTA, often incidentally diagnosed [see Figure 14 and Figure 15].

The scanning volume of CTA is determined by the indication. It is typical to start at the lung apices, which provides adequate coverage of the supra-aortic vessels. The end position is typically at the level of the midkidney; however, if a dissection is suspected, the coverage can be extended to the groin. Full assessment of aortic dissection by CT requires unenhanced CT followed by arterial phase contrast-enhanced CT. The unenhanced CT is useful for detection of dense intramural hematoma that may be mistaken for chronic thrombus on the enhanced images. ECG gating is usually reserved for the evaluation of aortic dissections, along with aortic root and ascending thoracic aortic aneurysmal disease,

Figure 18 A 45-year-old male presented with bilateral lower limb swelling and tenderness. Duplex ultrasonography diagnosed bilateral deep vein thrombosis extending above the inguinal ligaments. Because of the severity of limb symptoms, catheter-directed lysis was initiated, with a safety retrievable caval filter also inserted. On check venography, cavoileal stenosis was unmasked. A coronal computed tomographic scan acquired during the portovenous phase following iodinated contrast administration demonstrates the postprocedure result. There are bilateral kissing cavoileal stents in situ (*arrows*), along with the caval filter (*arrowhead*). Note that the thrombus has completely cleared following lysis.

Figure 19 A 36-year-old male with metastatic pancreatic cancer undergoing palliative care presented with gross bilateral lower limb painful edema. Duplex ultrasonography showed no evidence of deep vein thrombosis. An axial multidetector computed tomographic scan acquired in the portovenous phase demonstrates a metal biliary stent (arrowhead) in situ passing through the large pancreatic malignancy (star). There is marked anterior extrinsic compression of the inferior vena cava by the pancreatic tumor, with only a small residual caval lumen remaining (arrow).

as gating reduces cardiac and aortic motion and therefore reduces pulsation artifact.

Automated bolus tracking or test bolus triggering techniques can reliably obtain the optimal arterial phase by placing an ROI on the ascending thoracic aorta. An injection volume of 100 mL of high-concentration contrast agent (350 mg iodine/mL) at a flow rate of 5 mL/s is typically used. Images are acquired in the cranial to caudal direction with a slice thickness of 1.5 mm, a slice interval of 1.0 mm, and 0.6 mm of collimation.

CTA OF THE MESENTERIC ARTERIES

CTA allows excellent visualization of the mesenteric vasculature.⁵⁴ Aneurysms, thrombosis, stenosis or occlusion, dissection, and inflammatory processes affecting the mesenteric vasculature have been evaluated by MDCTA.

Mesenteric ischemia comprises three categories: acute arterial occlusion, nonocclusive ischemia (mesenteric angina), and venous thrombosis. Acute mesenteric ischemia is a life-threatening event that may be caused by a variety of etiologies. These include embolic phenomenon, severe hypoperfusion, thrombosis of an underlying arterial stenosis, dissection, hypercoagulable states (in situ thrombosis formation), and vasculitis. MDCTA with optimally timed contrast bolus can often readily delineate the site of arterial occlusion manifested by an abrupt cutoff of arterial contrast enhancement with complete occlusion or thrombus identified as a filling defect with contrast surrounding it in a nonocclusive thrombus. A combination of imaging planes, including the axial source images and the sagittal and coronal reformatted images, together with some curved multiplanar reformatted images, can increase the diagnostic yield. Although DSA remains the gold standard, it is usually reserved for cases

Figure 20 A 29-year-old female swimmer presented with left arm pain and intermittent swelling. (a) Coronal image from a direct magnetic resonance venogram (MRV) with injection of dilute gadolinium contrast via a left peripheral intravenous canula with the left arm adducted. There is no evidence of subclavian venous compromise at the level of the thoracic outlet (arrow). (b) Coronal image from a direct MRV with the left arm abducted demonstrates subclavian venous compromise with luminal narrowing at the level of the thoracic outlet (arrow). (c) Coronal maximum-intensity projection from a high-resolution magnetic resonance angiogram demonstrates no arterial compromise with the left arm abducted. Incidental note is made of a four-vessel aortic arch, with the right subclavian and the right common carotid arteries arising separately from the aortic arch.

requiring concurrent endovascular intervention, which is less likely in the acute setting as open surgery with embolectomy and bowel inspection is more desirable to restore mesenteric perfusion as rapidly as possible. CT accurately visualizes the portal, splenic, and superior mesenteric veins and can be used to diagnose mesenteric venous thrombosis.⁵⁵ Diagnosis of mesenteric venous thrombosis requires delayed images in the venous phase to avoid unopacified mesenteric veins, which can mimic thrombosis. Unenhanced images are also beneficial because they may show a hyperdense thrombus.⁵⁶ A pathognomonic finding of mesenteric venous thrombosis on CT includes an enlarged mesenteric vein with a low-density

center surrounded by an enhancing wall along with marked edema of the mesentery with bowel wall thickening [see *Figure 16*]. When evaluating for mesenteric vascular pathology, close attention to the morphology of the bowel is important as thickened bowel loops with thumbprinting, the presence of a sentinel loop or an ileus, secondary bowel wall hemorrhage or edema, pneumatosis (air within the bowel wall—a late sign that usually indicates dead infarcted bowel), and altered enhancement (either hyper- or hypoenhancement of the affected bowel) are signs of ischemia or infarction. Portal venous air is a late and often premonitory sign that can occur with a long segment of infarcted bowel.

Figure 21 An 18-year-old male presented with a painful mass in the left side of his neck and low-grade fevers. (a) Coronal reconstruction of a multidetector computed tomographic venogram was obtained and demonstrates a focal mass in the left supraclavicular region with a low-attenuation center (*star*) and an enhancing rim. There is extensive low-attenuation material within an expanded left brachiocephalic vein (*arrow*). (b) More posterior coronal reconstruction demonstrates further low-attenuation material within an expanded left internal jugular vein (LIJV) (*arrow*). Note that the material is also enhancing within the vein lumen (*arrowhead*). The focal mass in the left supraclavicular region with a low-attenuation center (*star*) and an enhancing rim is also seen. These findings are consistent with a septic thrombus within the LIJV extending into the left brachiocephalic vein as a result of the left supraclavicular abscess. This constellation of findings is known as Lemierre syndrome. The neck abscess was drained percutaneously under ultrasound guidance, and the patient was treated with intravenous antibiotics, with resolution of fevers.

Chronic mesenteric ischemia classically manifests clinically with the triad of postprandial abdominal pain, weight loss, and food avoidance. Atherosclerosis, causing severe stenosis or occlusion in at least two mesenteric arteries, is the usual etiology. CTA can accurately demonstrate the stenoses or occlusions, degree of calcification, and number of mesenteric vessels involved and serves as a pretreatment roadmap prior to stenting or bypass. The advantage of CTA over MRA is in the follow-up of stented patients as a result of the superior spatial resolution and lack of stent-related artifacts with CTA to determine stent patency and detect any in-stent restenosis. Other etiologies of chronic mesenteric angina can also be diagnosed with CTA, including fibromuscular dysplasia, vasculitis, radiation arteritis, and, albeit rarely, SMA syndrome [see Figure 17].

Celiac axis compression by the median arcuate ligament is known as median arcuate ligament syndrome and can lead to mesenteric angina; however, it is often asymptomatic. Additionally, this entity has been reported to predispose patients who have undergone orthotopic liver transplantation to hepatic artery thrombosis. If median arcuate ligament syndrome is suspected, imaging should be obtained during full inspiration to avoid artifactual stenosis.⁵⁷ Celiac and mesenteric stenoses are best visualized by sagittal thin-slab MIP or volume-rendered images. However, a thin-slab coronal MIP image also provides an excellent overview of the mesenteric vascular structures and the bowel loops. Treatment is surgical, consisting of release of the ligament, with no real

role for an endovascular option as a result of stent compression or even fracture. Although surgical treatment can lead to clinical improvement in symptomatic patients, the importance of celiac artery compression in asymptomatic patients is not established.

Most institutions will initially perform an arterial phase scan from the lower third of the chest above the diaphragm to the pubic symphysis; an optional initial noncontrast acquisition may be useful to see a high-attenuation thrombus, and venous phase timed acquisition covering the same scan range should also be obtained. Bolus tracking triggering can reliably obtain the optimal arterial phase by placing an ROI on the descending thoracic aorta above the diaphragm. An injection volume of 150 mL of high-concentration contrast agent (350 mg iodine/mL) at a flow rate of 5 mL/s is typically used. Images are acquired in the cranial to caudal direction with a slice thickness of 1.0 mm, a slice interval of 1.0 mm, and 0.6 mm of collimation.

COMPUTED TOMOGRAPHIC VENOGRAPHY

Duplex US is regarded as the first-line tool for diagnosis of lower and upper limb deep vein thrombosis (DVT); however, in certain clinical scenarios, particularly when interrogating the pelvic veins, computed tomographic venography (CTV) may be necessary to aid diagnosis for suprainguinal DVT. Venous phase contrast-enhanced CT can also be valuable in cases of May-Thurner syndrome with extensive thrombus prior to intervention with pharmacologic or mechanical

Figure 22 A 63-year-old female presents with lightheadedness and dizziness, particularly when grocery shopping. (a) Coronal maximum-intensity projection from a high-resolution contrast-enhanced thoracic aortic magnetic resonance angiogram demonstrates an occlusion of the right innominate artery (arrow) and a focal tight stenosis of the left subclavian artery (arrowhead). (b) Axial phase contrast magnetic resonance image obtained for flow directional information. Note that the antegrade flow is white in color and retrograde flow is black in color. There is forward flow (white) within both carotid arteries (arrowheads); note the smaller caliber of the right carotid artery compared with the left. There is reverse or retrograde flow (black) within the right vertebral artery (arrow) consistent with a right subclavian artery steal phenomenon. Note the normal retrograde flow within both internal jugular veins (stars).

thrombolysis and venoplasty and stenting [see *Figure 18*]. CTV can eloquently demonstrate the classical May-Thurner finding of left-sided common iliac vein compression by the overlying right common iliac artery, as well as the extent of thrombus and degree of venous stenosis.⁵⁸

Occlusion of the inferior vena cava (IVC) can be caused by both intrinsic and extrinsic [see *Figure 19*] diseases, and CT is sensitive for both thrombosis of the IVC and adjacent tumors causing caval compression. CT also clearly demonstrates caval anatomy, particularly congenital venous abnormalities such as duplication of the cava, circumaortic and retroaortic renal veins, left-sided cava, and, albeit rarely, persistent sciatic veins. These anatomic findings are most important to be aware of prior to any intervention; that is, the presence of a circumaortic or retroaortic renal vein will affect clamp position during open AAA repair, and the presence of a double IVC will potentially require two caval filters to prevent pulmonary embolus.

However, CTV can be technically difficult to perform as the timing of the contrast bolus is not as standard as for

arterial imaging, where an ROI is used to obtain the optimum contrast density within the artery of interest. Often a standard imaging delay is used, for example, 120 seconds after contrast administration; however, this does not take into account individual patient factors such as cardiac output, blood pressure, and body habitus. This contrast timing problem has been largely overcome with the use of MRV, where a time-resolved sequence can be used, analogous to the concept of DSA, where multiple acquisitions can be acquired at multiple time points, enabling imaging in both optimal arterial and venous phases with a number of phases in between [see *Magnetic Resonance Venography, below*].

CTA AND CTV OF THE THORACIC OUTLET

The thoracic outlet comprises a complex anatomic region with the brachial plexus, subclavian vein, and subclavian artery situated in a small enclosed space liable to compression. The most common symptoms occur from compression of the brachial plexus, followed by compression of the subclavian vein and least of all compression of the subclavian

Figure 23 A 59-year-old female presented with an acutely ischemic left leg. (a) Coronal maximum-intensity projection from a time-resolved magnetic resonance angiogram demonstrates an abrupt cutoff at the left tibioperoneal trunk (arrow). Note the patency of the left anterior tibial artery (arrowhead). (b) Thrombus was confirmed at angiography (arrow), and catheter-directed lysis was commenced.

Figure 24 A 41-year-old Asian female presented with left-sided claudication and an elevated erythrocyte sedimentation rate. (a) Coronal maximum-intensity projection (MIP) from a high-resolution abdominal magnetic resonance angiogram (MRA) demonstrates a mid-aortic narrowing with evidence of previous surgery with an aortobifemoral bypass (arrow). Note that the left limb of the aortobifemoral graft is occluded. There is enlargement of the median sacral artery (arrowhead), and large collaterals are present, allowing reconstitution of the left common femoral artery. (b) The same patient also underwent thoracic MRA. Coronal MIP from this high-resolution chest MRA shows evidence of a focal high-grade stenosis of the left subclavian artery (arrowhead), along with a short segment occlusion of the left axillary artery (arrow). This combination of findings, along with the elevated inflammatory markers, was consistent with Takayasu arteritis.

artery. As a result of the complex interrelation between muscles and neurovascular structures, CTA and CTV are particularly useful in the diagnosis of thoracic outlet syndrome and in preoperative planning. Matsumura and colleagues demonstrated the utility of CT in the sagittal plane and 3D reconstruction in patients with thoracic outlet symptoms and controls.⁵⁹ Three-dimensional CT reconstruction provides accurate details of cervical and abnormal first ribs, along with the presence of muscular hypertrophy of the scalene muscle occurring in thin athletic patients. Sagittal reconstruction was performed before and after abduction external rotation of the arm. Abduction external rotation allows the clavicle to pass upward on the first rib, producing occlusion of the subclavian vein, followed by subclavian artery occlusion. Three-dimensional CT reconstruction may also demonstrate abnormalities of the clavicle. Malunion and callous formation of clavicular fractures compromises the costoclavicular space, producing neurovascular compromise of the thoracic outlet. MRA and MRV may also be advantageous in the diagnosis of thoracic outlet syndrome [see Figure 20].

CTA AND CTV OF OTHER SITES

Rare etiologies are encountered on imaging intermittently, and although every syndrome or clinical condition is beyond the scope of this chapter, one such example presented is that of Lemierre syndrome [see Figure 21]. This consists of a septic thrombus within the internal jugular vein, which can cause severe life-threatening sepsis, including septic pulmonary emboli, and can be associated with neck abscesses.⁶⁰ Treatment consists of identification of the septic source, often necessitating abscess drainage and intravenous antibiotics, and may even require involved venous segmental resection.⁶⁰

Magnetic Resonance Angiography

With advancements in hardware and software over the last decade, MRI of the entire arterial tree has grown exponentially. Although DSA still remains the gold standard, there is no arterial or venous bed where MRA or MRV cannot be

used to establish a diagnosis of arterial or venous disease. The single most important advantage of MRA over CTA is that MRA does not require the use of ionizing radiation, thereby enabling serial examinations to be performed, particularly for aneurysmal surveillance over the life of the patient, and the lack of radiation is also of importance in scanning young patients. Moreover, MRA does not necessitate the use of nephrotoxic iodinated contrast medium; however, the gadolinium contrast agent used is not suitable for patients already in established renal impairment or failure because of the risk of nephrogenic systemic fibrosis (NSF), with the highest risk in patients with a glomerular filtration rate less than 30 mL/min.⁶¹ MRA, unlike CTA, can yield dynamic flow information analogous to that of DSA, with the use of time-resolved magnetic resonance (MR) techniques, which is particularly useful for the evaluation of below-knee arteries. Also, MRI can be used to glean physiologic information as phase contrast imaging can demonstrate arterial flow velocity and direction, which is most useful in diagnosing arterial steal phenomena. The common problem of calcification with its blooming artifact on CTA is also overcome by MRA as the calcium in atherosclerotic plaque manifests as a low signal on

MRA without the obscuring blooming artifact. In addition, MRA acquisition can be performed in a number of different imaging planes depending on the vessel of interest; that is, the thoracic aorta can be imaged in a left anterior oblique plane, analogous to the images one would acquire with conventional DSA.

However, MRA has its own limitations with respect to artifacts, particularly occurring in the setting of arterial or venous stents. Susceptibility artifact leads to signal dropout around the site of the stent, which leads to a signal void within the vessel lumen and thus limits the accuracy of assessing that particular arterial segment and the ability to diagnose in-stent restenosis. Although this problem is more pronounced for stainless steel stents compared with nitinol stents, stent geometry and strut orientation can also affect the degree of susceptibility artifact. Copper has been found to be a more desirable stent component to limit the degree of susceptibility artifact.⁶² Patients with certain implanted devices are not suitable to undergo MRA, such as intracranial clips and certain cardiac defibrillators; however, many centers have now successfully scanned patients with permanent cardiac pacemaker devices using a truncated scan technique. Currently, the obtained

Figure 25 A 59-year-old male with a previous open repair of a coarctation at 8 years of age. He presented again with bilateral claudication and underwent magnetic resonance angiography (MRA). (a) Coronal maximum-intensity projection (MIP) from a high-resolution MRA demonstrates recurrence of the coarctation (arrow) at the expected location within the descending thoracic aorta beyond the left subclavian artery (arrowhead). It was elected to treat his recurrent coarctation endovascularly. (b) Sagittal MIP from a time-resolved MRA poststenting demonstrates susceptibility artifact manifesting as signal dropout from the stent across the coarctation (arrow).

spatial resolution of MRI is inferior to that of CT, but with higher field strengths, spatial resolution can approach that of CT.

The most recent exciting advance in arterial MRA is the development of sequences that do not require administration of contrast media to obtain eloquent accurate MRAs, thus avoiding the risk of NSF development. Both CT and MRI are currently being extensively used for plaque imaging, where individual components of atherosclerotic plaque can be characterized and followed post-medical therapy or intervention.

BLACK BLOOD MRI

Black blood imaging is currently not heavily relied on in most vascular MRI practices. It is of use, however, to examine the wall of the aorta to evaluate atherosclerotic plaque and aortic wall thickening occurring in inflammatory

conditions such as large vessel vasculitides such as Takayasu arteritis and giant cell arteritis. Black blood imaging uses spin-echo (SE) and fast spin-echo (FSE) pulse sequences, which take advantage of the inherent contrast between rapidly flowing blood and the aortic wall and thus require no administration of intravenous contrast medium. Signal void occurs within the vessel lumen because of the movement of spins and dephasing of turbulent flow. A detailed description of MRI physics and pulse sequences is beyond the scope of this chapter.

BRIGHT BLOOD MRI

A number of bright blood techniques are used without the need for administration of intravenous contrast medium, with the most widely practiced method being the TOF technique. TOF is based on the phenomenon of flow-related enhancement of proton spins entering into a partially saturated

Figure 26 A 31-year-old male presented for follow-up for a coarctation corrected when the patient was a child. A coronal maximum-intensity projection image from a time-resolved magnetic resonance angiogram demonstrates a stenosis (arrowhead) of the proximal descending thoracic aorta just distal to the origin of the left subclavian artery. There is a large shunt identified from the apex of the left ventricle to the descending thoracic aorta consistent with a surgical bypass created to correct for the presence of this coarctation (arrow).

Figure 27 A 25-year-old male presented with claudication on running. A sagittal fast imaging with steady-state precession (FISP) magnetic resonance image of the thoracic aorta demonstrates a coarctation (arrow) and a persistent patent ductus arteriosus (arrowhead).

imaging slice. The protons that enter are unsaturated spins that give more signal than stationary spins within the previously saturated slice. Thus, in simple terms, a section of tissue is partially saturated with a radiofrequency pulse, which eliminates production of signal; arterial blood, which is unsaturated, then flows into this slice, and its spins are then able to produce a signal. During the acquisition, multiple thin, sequential sections are acquired in two-dimensions by using a flow-compensated gradient echo (GRE) sequence. These sections can be reformatted with the MIP technique to obtain a 3D image. Although the use of no contrast has inherent benefits, TOF has several limitations, including loss of signal if laminar flow is not present, resulting in false positives, poor performance in tortuous vessels, inability to appreciate retrograde flow in collaterals, and long imaging times. Despite these limitations, some advancements in the sequences have allowed vendors to develop two-dimensional cine mode TOF sequences, namely cine GRE, which are ECG gated and result in higher temporal resolution. These newer TOF sequences, known differently depending on the

vendor (true fast imaging with steady-state precession = FISP [Siemens], fast imaging employing steady-state acquisition = FIESTA [GE], and balanced fast field echo = FFE [Philips]), are useful in emergency settings as an aneurysm, rupture, large vessel thrombus, or dissection flap can be eloquently demonstrated.

Cine phase contrast is another noncontrast bright blood technique that can be used for dynamic evaluation of blood flow to demonstrate flow velocity and direction. Cine phase contrast depends on the phase shifts that flowing protons experience as they travel along the gradient field. Direction is manifest by bright or dark pixels, and velocity is represented by relative signal intensity. This technique is particularly useful for diagnosing steal phenomena such as subclavian steal [see Figure 22].

CONTRAST-ENHANCED MRA

Contrast-enhanced magnetic resonance angiography (CE-MRA) has revolutionized the use of MRI in the diagnosis of vascular disease as this technique can yield good-quality,

Figure 28 A 79-year-old female presented with three episodes of right-sided transient ischemic attacks. Maximum-intensity projection from a contrast-enhanced carotid and aortic arch magnetic resonance angiogram demonstrates a tight, greater than 90% stenosis of the left internal carotid artery (arrow). This was repaired surgically.

Figure 29 A 56-year-old male presented with right-sided one-block intermittent claudication 1 week following coronary angiography. A coronal maximum-intensity projection image from a time-resolved magnetic resonance angiogram demonstrates a short focal occlusion of the right common femoral artery (CFA) (arrow). Note that some small collaterals are present, allowing reconstitution of the right profunda femoris and superficial femoral artery. There is a discrepancy in the contrast density between the two limbs being denser on the left, consistent with poorer flow on the right side. This short focal occlusion was secondary to a closure device and required surgical repair with a right CFA patch plasty.

accurate angiograms that can be manipulated, via post-processing techniques, in all imaging planes, in a fast timely manner with no radiation dose to the patient.

The principle used by CE-MRA is that of T_1 shortening produced by the gadolinium contrast agent. Intravenously administered gadolinium circulates within the bloodstream and shortens the T_1 so much that blood is rendered bright irrespective of the flow patterns or velocities, thus avoiding the limitations of the bright blood TOF technique. Signal enhancement and overall image quality of CE-MRA depend on the intra-arterial concentration of the contrast agent; therefore, correct timing of imaging after contrast material injection is crucial. Thus one must image when the contrast bolus is within the desired vessel of interest, analogous to the concept of contrast timing for CTA. Similar to CTA, a number of methods are available to optimize contrast timing, including injection of a test bolus using a small amount of contrast material, automatic triggering using an ROI, and

Figure 30 A 61-year-old male with three-block intermittent claudication presented for evaluation. Coronal maximum-intensity projection from a high-resolution magnetic resonance angiogram demonstrates a mid-superficial femoral arterial complete occlusion (arrow) with a large collateral (arrowhead) and multiple small collaterals. This was treated endovascularly with a 6 mm stent.

Figure 31 A 39-year-old male athlete with bilateral claudication when running. (a) An axial contrast-enhanced magnetic resonance image at the left popliteal fossa demonstrates the popliteal artery (arrow) separated from the popliteal vein (arrowhead) by a muscular band (star), which is from the medial head of the gastrocnemius muscle. This finding is consistent with popliteal arterial entrapment syndrome. (b) Coronal maximum-intensity projection from a time-resolved magnetic resonance angiogram with the patient in plantar flexion demonstrates occlusion of both right and left popliteal arteries (arrows) with some reconstitution distally. This is consistent with bilateral popliteal arterial entrapment.

MR fluoroscopy. Contrast volume is determined on an individual patient basis per weight, with a single dose being 0.1 mmol/kg; for CE-MRA, at least double the dose is usually administered. Based on the Fourier nature of MRI data acquisition, image contrast depends mainly on central k-space data; thus, collection of the central lines of k-space during the plateau phase of arterial enhancement is essential for optimal CE-MRA. Image fine detail depends on peripheral k-space data, which may be collected before and/or after the gadolinium peak to enhance MRA image resolution.

Repetition times (TRs) used for CE-MRA are approximately 5 milliseconds or less, with echo times (TEs) of 1 to 2 milliseconds and total scan times ranging from 10 to 30 seconds, thus fast enough to acquire all of the data in one breath-hold. Many other tricks can be employed to perform time-resolved MRA, which is a dynamic MRA technique almost analogous to the concept of rapid imaging frames obtained during DSA. A combination of ultra-short TR, parallel imaging, partial Fourier transform, sharing of peripheral k-space data, and sliding window reconstruction with

radial or spiral trajectories makes time-resolved (TR) CE-MRA possible at subsecond temporal resolution. TR-MRA is particularly useful in evaluating the peripheral runoff arteries, where traditional high-resolution CE-MRA can be limited by discordant flow bilaterally, contrast bolus timing issues, and consequent venous overlay [see Figure 23].

Postprocessing of the CE-MRA source data is somewhat easier and less time consuming than that of CTA data as the contrast-filled vessel is the brightest structure for the MRA MIP image because the calcium is of low signal on MR, unlike the high attenuation of calcified plaque and bone on CT. As with CTA, image interpretation is performed on a computer workstation, where the source images are analyzed and postprocessing techniques, including multiplanar reformation, MIP reformation, and volume rendering, are used.

THORACIC AORTIC MRA

Thoracic aortic aneurysmal disease is particularly suited to diagnosis and follow-up with CE-MRA as MRA is highly accurate, is reproducible, and incurs no radiation dose for

Figure 32 A 29-year-old male presented with a painful left lower limb with some skin discoloration. (a) Coronal maximum-intensity projection (MIP) from a time-resolved peripheral magnetic resonance angiogram (MRA) demonstrating both lower limb runoff vessels. Although this is within the arterial phase of contrast injection, early draining veins are identified on the medial aspect of the left lower limb with a small nidus (arrowhead). (b) Coronal arterial phase time-resolved MIP more proximal within the thighs demonstrates a large left great saphenous vein (arrow) with varicosity (arrowhead). As directionality of the flow can be determined with dynamic time-resolved MRA, it was noted that the direction of flow was from the nidus in the cephalad direction, confirming arteriovenous malformation with varicosity, as opposed to reflux from the saphenofemoral junction or perforators, which would result in flow in a caudal direction and manifest as venous insufficiency with varicose veins.

the patient. Also, MRI can be used to evaluate the adjacent aortic valve for anatomy (bicuspid or trileaflet), stenosis, or regurgitation, all of which are vital to know prior to an ascending aortic aneurysm repair to determine if the surgery is valve sparing or necessitates a concomitant aortic valve replacement. Acquiring the CE-MRA images in the oblique sagittal plane allows for almost the entire aorta to be visualized, which is useful for thoracoabdominal aneurysms and type B dissections.

Aortic dissection, along with its complications of coronary artery involvement, aortic valve rupture, pericardial hemorrhage with tamponade, branch vessel involvement, visceral ischemia, and peripheral ischemia, can be reliably diagnosed with MR using both noncontrast bright blood imaging techniques—mainly the new steady-state free precession (SSFP) techniques such as FISP, FIESTA, and FFE—and CE-MRA. Techniques such as FISP can rapidly diagnose and determine the extent of aortic dissection in a few minutes, without the need for breath-hold, contrast, or radiation. Cine FISP through the aortic valve can rapidly assess function, and a stack of short axis slices through the heart can determine any ventricular wall motion abnormalities that may be seen with coronary artery involvement resulting in myocardial infarction, along with tamponade physiology; however, there are obviously other methods to diagnose these complications, such as transthoracic or transesophageal echocardiography. Previously, SE black blood sequences were also used to demonstrate the intimal flap, usual signal void in the true lumen, and high signal attributable to slow flow or thrombus within the false lumen. CE-MRA can eloquently confirm the diagnosis, differentiate thrombus from slow flow within the false lumen, and diagnose complicated type B dissection with visceral or peripheral ischemia that may need endovascular or surgical intervention.

The limitations of MRI are availability, MR-compatible vital sign monitoring equipment, and fear of placing an unstable patient in the magnet. However, in high-volume centers with 24-hour access to magnets and staff experienced in monitoring unstable patients within the MRI scanner, this modality offers a viable alternative to CTA and TEE, especially in the setting of an iodinated contrast allergy or renal impairment.

Intramural hematoma, regarded by many as a spectrum in the same disease process as dissection, can be differentiated from dissection with thrombosis of the false lumen with the use of different sequences, namely cine GRE. SE can be used to age the thrombus with intermediate signal attributable to oxyhemoglobin in the acute setting and high signal attributable to methemoglobin in the more subacute setting.

Large vessel vasculitides such as Takayasu arteritis and giant cell arteritis are well suited to evaluation with MRI and CE-MRA. Aortic and branch vessel wall thickening can be diagnosed even before the occurrence of luminal compromise and/or dilatation. Aortic wall thickness can be demonstrated readily on fat-suppressed T_1 -weighted (T_1W) MRI, and edema is seen as a hyperintense intramural signal on T_2 -weighted (T_2W) imaging. Mural hyperenhancement of the aortic or arch vessel wall on fat saturation T_1W images after injection of contrast material is considered to indicate active inflammation; thus, a delayed postcontrast T_1W image is

obtained after the CE-MRA portion when considering large vessel vasculitis. The CE-MRA portion of the study identifies the involved segments of the aorta and its branch arteries. Takayasu arteritis classically causes proliferation of the intima, with medial and adventitial fibrosis, which subsequently leads to segments of arterial stenosis, occlusion, and/or poststenotic dilatation, usually affecting the aorta and its arch branches in a patchy distribution [see Figure 24].

Coarctation usually presents in childhood but occasionally can present in adulthood or recur in adulthood. MRA is an eloquent way to demonstrate the coarctation or the previous repair [see Figure 25a, Figure 26, and Figure 27]. However, once a coarctation is stented, MRA becomes limited in its ability to follow up the patient because of the susceptibility artifact encountered [see Figure 25b].

ABDOMINAL AORTIC MRA

CE-MRA has been shown by a number of authors to have a high sensitivity and specificity, both 100%, for the diagnosis of AAA.⁶³ The important information for preprocedural planning can be gleaned from MRA, including location, size, extent, adjacent arterial branch anatomy, thrombus load, and 3D spatial relations. Importantly, when measuring the size of an AAA on MRA, the source images and not the MIP images should be used to see the wall of the aorta and thus not underestimate the size of the aneurysm on the MIPs. However, to date, most centers continue to perform pre-EVAR planning with CTA. Post-EVAR follow-up can be performed with CE-MRA to detect endoleaks and monitor sac size; however, the stainless steel stent grafts cause marked susceptibility artifact and are contraindicated for MRI per the manufacturer's guidelines. Open aneurysm repair is not without its flaws, and CE-MRA can be used to detect potential complications such as para-anastomotic aneurysms, infections, graft occlusions, and venous or enteric fistulae. Graft infections, when confirmed, usually require complex surgical intervention with removal of the graft material and extra-anatomic bypass grafting; however, infection can often be difficult to diagnose. MRI can aid in the diagnosis by using fat-suppressed T_1W and T_2W imaging, along with delayed contrast enhanced fat-suppressed T_1W images. The presence of fluid surrounding the graft (bright on T_2W , dark on T_1W), surrounding muscle edema (bright on T_2W), and delayed peripheral contrast enhancement on fat-suppressed T_1W images are all signs of graft infection.⁶³

MRI is rarely used in the acute setting of suspected AAA rupture, again for the reasons outlined in the section on thoracic aortic MRA above.

CAROTID MRA

A recent meta-analysis examining noninvasive imaging modalities for diagnosis of carotid artery stenosis determined that contrast-enhanced MRA seems to be the most accurate noninvasive imaging test,⁵⁰ compared with US and MDCTA, and this finding is concordant with that of an earlier systematic review.⁶⁴ Sensitivity and specificity for CE-MRA for the diagnosis of 70 to 99% NASCET stenosis were in the order of 85% (95% CI 0.69 to 0.93) and 85% (95% CI 0.76 to 0.92), respectively,⁵⁰ and 94% (95% CI 0.88 to 0.97) and 93% (95% CI 0.89 to 0.96), respectively.⁶⁴ The results were not as accurate, in either meta-analysis, in the diagnosis of

Figure 33 A 69-year-old male presented with acute onset of diffuse abdominal pain. Axial (a) and coronal (b) postcontrast fat saturation T₁-weighted magnetic resonance images through the upper abdomen demonstrate a filling defect within the superior mesenteric artery (SMA) (arrows) with contrast enhancement of the adjacent superior mesenteric vein (arrowheads). (c) Sagittal maximum-intensity projection from a high-resolution contrast-enhanced magnetic resonance angiogram demonstrates an abrupt cutoff of the SMA (arrow) consistent with an embolus or in situ thrombus. This was successfully treated with surgical embolectomy.

carotid artery stenosis in the order of 50 to 69% per NASCET reporting criteria.^{50,64}

MRA, including the aortic arch and circle of Willis, can provide an excellent preprocedural extra- and intracranial roadmap, which can reduce the number of DSA runs and total contrast volume used during carotid stenting, thereby

reducing catheter dwelling time within the aorta and carotid artery [see Figure 28].

Again, MRI is limited in the stented patient because of susceptibility artifact; however MRI is an excellent tool for the post-CEA patient to detect any postoperative complications. Carotid patch infection, along with its complications of

Figure 34 A 45-year-old female presented for evaluation of menorrhagia and underwent pelvic magnetic resonance imaging (MRI). Of note, she had an episode of blunt trauma 5 months earlier. (a) Coronal T₁-weighted fat saturation postcontrast pelvic MRI demonstrates a 1 cm focal area of enhancement within the left posterior pelvis (arrow) with evidence of a feeding vessel (arrowhead). (b) Axial T₁-weighted fat saturation postcontrast pelvic MRI confirms the presence of a 1 cm pseudoaneurysm from the inferior gluteal artery (arrow). This was successfully coil embolized.

abscess formation, pseudoaneurysms, and blowout, is universally feared. MRI can be useful in this setting, similar to the diagnosis of infected abdominal aortic grafts, as described above.

PERIPHERAL MRA

A large meta-analysis determined that the sensitivity and specificity of CE-MRA in diagnosing peripheral arterial stenoses is 94% and 90%, respectively.²⁸ When compared with MDCTA and duplex US for diagnosing peripheral arterial stenoses greater than 50% in another large meta-analysis, CE-MRA had a sensitivity and a specificity of 95% and 97%, respectively, with MDCTA at 91% and 91%, respectively, and duplex US at 88% and 96%, respectively.¹³ Where patients indicated a preference for imaging modality, MRA, with or without contrast, was chosen.¹³ Therefore, many centers are now using MRA as the first-line imaging tool for

determining the extent of PAD. The ABI remains the first-line noninvasive test to diagnose PAD; however, the ABI has a limited role in determining the extent of disease and in preprocedural planning. MRA has the ability to produce conventional “angiogram”-like images, which are easy to interpret and provide an accurate roadmap prior to open or endovascular intervention, thereby eliminating the need for DSA in the vast majority of cases [see Figure 29].

The usual MRA imaging protocol consists of initial scout images of the abdomen, pelvis, and lower limbs, usually with a dedicated peripheral coil. At our institution, a time-resolved MRA of the runoff vessels is obtained first to eliminate the problem of venous overlay and missed timing of the contrast bolus. This time-resolved technique uses parallel imaging and k-space under sampling with echo-sharing to increase temporal resolution at the expense of spatial resolution. This technique produces a dynamic “run,” analogous to a DSA “run,” which yields information on asymmetrical arterial contrast opacification, flow direction, collateral filling, and retrograde filling of diseased arterial segments [see Figure 30]. A three-station (pelvis, thigh, and runoff) high-resolution MRA is then acquired with a mask image performed at each station followed by a rapid acquisition with peak arterial gadolinium enhancement at each station with incremental table movement between stations. Usually, a double dose of gadolinium (0.2 mmol/kg) is required.

Figure 35 A 32-year-old female with hypertension undergoing workup for cause. Coronal maximum-intensity projection from a high-resolution contrast-enhanced magnetic resonance angiogram. There is evidence of bilateral nonostial beading of both main renal arteries (*arrowheads*), with no significant stenosis. This finding is consistent with fibromuscular dysplasia. This was successfully treated endovascularly with balloon angioplasty.

Figure 36 A 34-year-old female undergoing workup to donate a kidney to her sister. Coronal maximum-intensity projection from a time-resolved magnetic resonance angiogram demonstrates a 2.1 cm right renal artery saccular aneurysm (*arrow*).

MRI is well suited to evaluate nonatherosclerotic conditions such as popliteal entrapment syndrome because of its ability to demonstrate the vessel lumen and the surrounding popliteal fossa anatomy to determine if the artery-muscle relation is normal. [see Figure 31]. Dynamic MRA can be performed with the foot in both dorsiflexion and plantar flexion to elicit the popliteal arterial compression, which is characteristic of the syndrome. MRA commonly shows a normal popliteal arterial lumen with the foot in the relaxed neutral position, with narrowing of the arterial lumen during stress maneuvers. Venous compression, stenosis, or occlusion with or without thrombus can also be clearly demonstrated by acquiring images in the venous phase.

Limb AVMs and venous malformations are eloquently characterized with MRI⁶⁵; in particular, time-resolved MRA with the high temporal resolution can demonstrate the high- or slow-flow characteristics and nidus localization, and any connections to deep veins can be identified [see Figure 32]. This information is vital for treatment planning with percutaneous alcohol or sclerotherapy for the low-flow malformations and with intra-arterial embolization therapy reserved for high-flow malformations.

MESENTERIC MRA

Previously, a small study demonstrated that CE-MRA had a 100% sensitivity and a 95% specificity for diagnosis of significant stenosis (> 75%) or occlusion of a mesenteric artery, compared with the gold standard of DSA.⁶⁶

In acutely unwell patients suspected of acute mesenteric ischemia, simple noncontrast MR using an SSFP sequence such as FISP can identify arterial occlusion without the need for contrast or breath-hold; also, bowel wall evaluation can be performed [see Figure 33]. However, in most centers, CTA is the preferred imaging option for the acute setting.

Occasionally, contrast-enhanced MRI, which is performed for other indications, can incidentally identify arterial pathology [see Figure 34].

RENAL MRA

A meta-analysis evaluating five noninvasive methods to diagnose RAS concluded that CE-MRA and MDCTA were significantly better at diagnosing RAS than duplex US, captopril renal scintigraphy, and captopril testing.⁶⁷ Also, there was no significant difference in diagnostic performance between CE-MRA and MDCTA.⁶⁷ However, when CE-MRA and MDCTA were compared with DSA in 402 patients with hypertension suspected of RAS, the combined sensitivity and specificity were 62% and 84%, respectively, for MRA versus 64% and 92%, respectively, for MDCTA.⁶⁸ The authors concluded that both CE-MRA and MDCTA were not reproducible or sensitive enough to rule out RAS; however, the specificity was adequate.⁶⁸ Therefore, when the study is negative, a conventional angiogram is not needed, but when a study is positive, then an angiogram may be needed prior to intervention. However, recent results from the ASTRAL trial demonstrated no significant clinical benefit on renal function or blood pressure control with renal stenting compared with best medical management in the majority of patients.⁶⁹ Therefore, given the lack of significant benefit from endovascular intervention, one can argue that noninvasive imaging is sufficient for the evaluation of RAS as CE-MRA can confidently

rule out RAS. If RAS exists, noninvasive imaging can overcall the degree of stenosis rather than miss the disease. Overcalling is relevant only if one is planning an intervention as one would not perform angioplasty or stent a true 30% stenosis (called as 60% on MRA); however, one would treat a 30%

Figure 37 A 29-year-old female presented with a swollen right lower limb. (a) Axial contrast-enhanced fat saturation T₁-weighted magnetic resonance image through the pelvis, acquired in the venous phase, demonstrating an enlarged enhancing venous structure posterior within the right pelvis consistent with a congenital anatomic variant of a persistent sciatic vein (arrow). Note the presence of both iliac venous systems (arrowheads). (b) Coronal maximum-intensity projection from the time-resolved magnetic resonance venogram demonstrating the right persistent sciatic vein (arrow).

stenosis medically. Thus, now perhaps the function of noninvasive imaging is to rule in or out the disease, with less importance on the absolute degree of stenosis, and to rule out other etiologies of hypertension [see *Figure 35* and *Figure 36*].

MAGNETIC RESONANCE VENOGRAPHY

A small study comparing CE-MRV with DSA determined that the overall sensitivity, specificity, and accuracy for the detection of portal, splenic, or superior mesenteric venous thrombosis were 100%, 98%, and 99%, respectively, for MRV and 91%, 100%, and 96%, respectively, for DSA.⁷⁰

MRV can be useful for problem solving for venous disease within the lower limbs. In patients with extensive upper thigh varicose veins in conjunction with perineal varicosities, MRV can be useful to diagnose pelvic venous congestion syndrome. Occasionally, unusual anatomic venous variants can present, and as these often manifest in young patients, the lack of ionizing radiation necessary for MRV makes it a better choice than MDCTV [see *Figure 37*].

33 ANTERIOR RETROPERITONEAL SPINE EXPOSURE

Theodore H. Teruya, MD, and Ahmed M. Abou-Zamzam Jr, MD

Anterior surgical exposure of the lumbar spine is a technique that has been increasingly performed by a host of general and vascular surgeons over the past decade to aid spinal surgeons. Whereas anterior spinal approaches were once reserved for rare spinal disorders such as tumors or infections, the development of spinal instrumentation has led to many commonly encountered spinal disorders, such as lumbar disk disease and spondylolisthesis, being treated through an anterior approach. Owing to the predominance of spinal pathology at the lower lumbar levels and the spinal surgeons' need for assistance with anterior approaches, the "exposure surgeon" has emerged.

The knowledge and expertise in dealing with the structures encountered in the anterior exposures lie within the field of general surgery. Manipulation of diverse structures, including the small bowel, colon, ureter, aorta, and iliac vessels, must be done with precision and is an excellent opportunity for the surgeon to provide added expertise to aid the spinal surgeon in obtaining a successful outcome.

This chapter covers the aspects of anterior surgical exposure of the spine relevant to the exposure surgeon. A brief review of the background, pathophysiology, and clinical presentation of lumbar spine disease is presented, followed by a review of the treatment options and preoperative evaluation. The technical aspects, including the relevant anatomy, exposure techniques, and conduct of the operation, are presented. The routine postoperative management of these patients and frequently encountered complications are reviewed. Important but rare situations, such as redo anterior approaches, are discussed. These areas are all important for the exposure surgeon to understand and master to safely provide optimal anterior spinal exposures and offer an important avenue for the surgical trainee to gain experience with open surgical techniques.

Background

Anterior lumbar interbody fusion was first described for Pott disease of the spine.¹ This approach has gained popularity in treating a variety of diseases of the spine. Over the past decade, a broad range of lumbar pathology has been treated with instrumentation requiring an anterior approach. General, vascular, and trauma surgeons are often enlisted to provide exposure of the spine. Anterior fusion and disk replacement procedures have become common, especially with the development of anterior lumbar interbody fusion and total disk arthroplasty. The spinal pathology addressed during the anterior exposures may be divided into diseases that affect the intervertebral disk and diseases that involve the

vertebral bodies along with the disk. The most common sites of involvement are the fourth and fifth lumbar vertebrae and the intervertebral disks between L4 and L5 and L5 and the sacrum (S1).

Knowledge of retroperitoneal anatomy is essential to the successful performance of these procedures. The iliac vessels will often need to be mobilized to gain access to the anterior aspect of the lumbar spine. During this mobilization, injury to the vessels may occur. Injuries to the iliac vessels are uncommon; however, when these injuries occur, life-threatening hemorrhage may result. Having a surgeon who can repair these injuries and perform the exposure can potentially reduce the chances of complications and optimize patient outcomes.

Pathophysiology

Isolated intervertebral disk disease is believed to be a major cause of chronic low back pain. The intervertebral disk is generally an avascular, fluid-rich structure that consists of the outer collagenous annulus fibrosus and the inner gelatinous nucleus pulposus. The intervertebral disk serves to absorb and dissipate loads on the spinal column and allows motion. With aging, desiccation and loss of disk height are universal. Back pain may result from internal disk disruption (IDD), disk herniation, or degenerative disk disease (DDD).

Discogenic pain is primarily attributable to IDD and DDD. IDD is marked by the presence of normal disk anatomy. This generally affects younger patients who present with back pain without radiculopathy. As the intervertebral disk is avascular and poorly innervated, pain is postulated to result from the leak of noxious chemicals.² In this manner, the disk serves as a "pain generator," and removal of the disk can lead to relief of pain. In contrast, DDD is marked by changes in the intervertebral disk architecture. In this setting, neurovascular ingrowth into the degenerated disk may lead to pain. The adjacent end plates and vertebral bodies may also serve as pain generators. Mechanical changes occur with DDD, which can lead to pain as a result of loading and alignment changes.

Bony abnormalities of the lumbar spine frequently treated by the exposure surgeon include lumbar spondylolisthesis. Spondylolisthesis exists when there is actual forward translation of one vertebral body over another with an intact neural arch. This misalignment and change in mechanical stress can lead to back pain secondary to muscular strain as well as potential nerve impingement with radicular pain. Often with these processes, the changes in alignment can lead to a change in disk structure and worsening pain. The pain is mechanical and aggravated by back extension or on arising from a bent

posture. Radicular leg pain or neurogenic claudication may exist. For spondylolisthesis to exist, there must be both disk disruption and ligamentous disruption. Therefore, therapies to treat this address both the disk and the vertebral alignment.

Clinical Presentation

Most of the types of lumbar spine pathology discussed above typically present with back pain. Radicular pain indicates nerve root impingement. These processes are more common in women and present in the fourth decade.² Back pain without radiculopathy, sitting intolerance, and increased pain with flexion, rotation, and bending are common complaints. Symptoms include low back pain, which is often made worse with long periods of standing or sitting. The postural relation and alleviating factors are important in differentiating lumbar disease from other pathologies. DDD may be accompanied by radiation to the sacroiliac joints, buttocks, and thighs. Spinal stenosis attributable to disk herniation may lead to lower extremity complaints but can be differentiated from vascular claudication by (1) the long time needed for recovery and (2) alleviation of pain by leaning forward and removing pressure on the spine. The presence of any atherosclerotic risk factor is a very important historical consideration. Physical examination in a patient with spinal stenosis may reveal pain with straight leg elevation, limited mobility, significant kyphosis, and tenderness over the lower spine.

Imaging modalities play a large role in the diagnosis of lumbar pathology. Plain x-rays may demonstrate a loss of disk height, bony abnormalities, and spondylolisthesis. Flexion and extension views are important. Magnetic resonance imaging (MRI) may demonstrate the “black disk” phenomenon. The significance of this finding is debated as this may often be seen in asymptomatic patients.² Discography is frequently performed to elicit the pain and to correlate the findings with other imaging studies. A computed tomographic (CT) scan can be combined with the discogram for additional information on disk architecture, and spinal stenosis. Imaging abnormalities may have a high false positive rate as 30% of asymptomatic patients will have abnormal imaging. Therefore, the diagnosis of lumbar spine disease must be based on sound clinical judgment, taking into account the history and physical examination and all imaging studies.

Treatment Options

Although the treatment of lumbar disk disease and spondylolisthesis has undergone significant evolution, the stepwise approach is needed. Nonoperative therapy is an essential first step. Patient education and activity modification are important initial treatments. Physical therapy and antiinflammatory medications are important cornerstones in patient management. The importance of appropriate pain control is clear; escalation of therapy is dependent on the response of the patient. Surgical therapy is reserved for failures of all less invasive therapies. Several less invasive surgical procedures may be offered to the patient, such as intradiscal electrothermal therapy, nucleus replacement, kyphoplasty, and other evolving treatments within the armamentarium of the spinal surgeon. However, the most invasive treatments, such as

anterior lumbar interbody fusion and disk arthroplasty, are the procedures of interest to the exposure surgeon.

Intervertebral disk disease is approached with two options: motion preservation or fusion. Lumbar fusion has been traditionally performed with a posterior approach. However, with new developments in instrumentation, the fusion can also be performed with an anterior approach.^{2,3} The anterior approach offers several advantages over posterior instrumentation and fusion. Anterior lumbar interbody fusion (ALIF) avoids the disruption of the muscular stability of the back and potential nerve root injury. Anterior fusion also produces a larger fusion surface, more complete disk decompression, and improved outcomes. ALIF was initially reserved for failures of posterior fusion, but with the improved results, ALIF may now be offered as the primary surgical treatment. The goal of all fusion procedures is to eliminate motion at the intervertebral space, restore alignment, and alleviate pain.

Although fusion has been successful in treating isolated intervertebral disk disease, recent investigations have established the options for motion-preserving therapy in affected patients.⁴ The development of total disk replacement (TDR) has the potential to preserve motion at the treated disk space while eliminating the disk as a source of pain. Preservation of motion at the disk space can avoid the late sequelae of adjacent-level degeneration seen above a previous spinal fusion. Prospective, randomized trials have demonstrated the superiority of TDR to ALIF in selected patients.⁵⁻⁸ This has important implications for the exposure surgeon: although fusions may be performed from a posterior approach, all currently available TDR systems in the United States require an anterior approach to the lumbar spine.

The treatments available for spondylolisthesis include decompression alone and decompression with fusion. Simple decompression may be chosen in high-risk patients and those with limited slip. However, prospective, randomized trials have demonstrated that the addition of fusion to decompression leads to improved outcomes.⁹ This has led to increased use of fusion for the treatment of spondylolisthesis, with anterior fusion demonstrating greater success than posterior fusion. Along with the fusion, anterior instrumentation with plates and screws is necessary when anterior columnar support is inadequate.³

Preoperative Evaluation

A thorough understanding of the background and treatment options for lumbar spine disease enables the exposure surgeon to fully participate in the treatment of these patients and not function as a mere technician. The importance of teaming with an experienced spinal surgeon with sound judgment cannot be overemphasized. Exposure surgeons must develop their own preoperative approach to the patient that maximizes the opportunity for success.

Once a patient has been selected as a candidate for anterior spinal surgery, a thorough evaluation by the exposure surgeon should be performed in a preoperative office visit. Given the magnitude of the operation and the central role the exposure surgeon plays, establishing a relationship with the patient is very important. Given the different perspectives of the spine and exposure surgeons, important additional information may be gleaned from the exposure surgeon's assessment.

A thorough medical history is an essential first step. Most patients who require this type of surgery tend to be young and otherwise healthy. Some patients will be overweight because of inactivity from their spine disease. Significant comorbidities that may place the patient at high risk for surgery must be considered at this point. General health issues, with an emphasis on atherosclerotic risk factors such as diabetes, hypertension, and tobacco use, should be queried. Previous surgical interventions, including previous abdominal operations, must be reviewed. Previous spinal surgery, even procedures from a posterior approach, can have implications related to scarring, instrumentation, and infection that can complicate an anterior approach.

A physical examination with special attention to body habitus, planned incision site, and previous surgical incisions should be performed. In all patients, a thorough pulse examination must be documented. The presence of significant vascular disease should be a relative contraindication to any anterior approach given the potential for vascular calcification and injury. If aortoiliac occlusive disease is suspected, noninvasive vascular studies may aid in the evaluation of patients with the potential presence of vascular disease by history or physical examination.

A review of all available imaging studies should be performed by the exposure surgeon. This will ensure that the approach surgeon understands and reviews the relevant anatomy. Available x-rays will demonstrate any vascular calcification, which may then suggest the need for further vascular imaging. The relevant vascular anatomy demonstrating the relation of the lumbar level of interest and the aortic bifurcation, confluence of iliac veins, and course of the iliac arteries and veins can often be determined from MRIs or CT scans. These scans can also demonstrate the presence of arterial calcification, surgical clips from previous operations, and other findings that may alter the considered approach. This will allow the exposure surgeon to have the clearest understanding possible to formulate an effective surgical plan.

A key part of any surgical procedure involving more than one specialist is communication. After the preoperative visit, the exposure surgeon should contact the spine specialist and review the case. This will minimize any potential for confusion at the time of surgery. At all stages, the exposure surgeon must be open and forthcoming, with both the patient and the spine surgeon, regarding expectations of the proposed surgery. It is important to remember that not all patients are good candidates for anterior spinal surgery. Previous colon surgery, retroperitoneal dissection, pelvic irradiation, or the presence of aortoiliac occlusive disease should be considered relative contraindications. Overall physiologic status is important and should be carefully considered prior to committing the patient to any major operation. The spine disorders treated via the anterior retroperitoneal approach are almost never life threatening; therefore, if the surgeon performing the exposure feels that the surgery will carry excessive risk, the procedure should be reconsidered.

Vascular Anatomy and Variations

The arterial anatomy is relatively simple, and variations rarely pose any difficulty in exposure of the disk levels. The arterial structures of importance include the aorta and the

bilateral common iliac arteries. Most mobilization involves the left common iliac artery, but exposure usually does not require division of any significant branches. If exposure of the disk levels cephalad to the L4-L5 level is necessary, then division of segmental lumbar arteries may be required.

Although the arterial anatomy is simple, the venous anatomy will require intraoperative assessment to determine the best method for exposure. At certain levels, typically L4-L5, mobilization of the iliac veins is essential to gain proper exposure to the lumbosacral spine. The venous anatomy in this area can be variable, and if there is improper mobilization of the veins, injury can occur, and this can lead to large blood loss.

The inferior vena cava originates at the confluence of the left and right common iliac veins. This usually occurs at the L4-L5 disk level; however, this can be variable. The left common iliac vein has tributaries that are known as the ascending lumbar vein (ALV) and the iliolumbar vein (ILV) [see Figure 1]. The ALV commonly arises from the lateral aspect of the common iliac vein. This vein will need to be divided to properly mobilize the left common iliac vein. The ILV can arise near the ALV or may arise more distally. Unruh and colleagues demonstrated that the venous anatomy can be variable and categorized the tributaries of the left common iliac vein into three types.¹⁰ More than half of the patients will have a common origin of a venous branch from the left common iliac vein, which then divides into the ALV and ILV. The other common variants both include two distinct origins for the ALV and ILV. The authors have proposed referring to these veins as the lateral lumbosacral veins because of the variation often encountered.¹⁰ The importance of this anatomy lies in the fact that these veins can be easily torn with medial retraction of the left common iliac vein and result in severe hemorrhage that is difficult to control. Mobilization and division of these key branches are necessary for full retraction of the left common iliac vein. It is important to note that although there can be significant variation of the venous anatomy in this area, careful dissection can avoid serious venous injuries in nearly all cases, and usually no more than two veins in this area need to be divided.

Operative Approach

GENERAL CONSIDERATIONS

The lumbar spine is most frequently diseased at the levels of the fourth lumbar vertebra through the sacrum (L4-S1). The anterior approach to the spine at these levels will therefore have to address the peritoneal and retroperitoneal structures overlying the spine at these levels. Employing an extraperitoneal approach can minimize the need to directly address the intraperitoneal structures. The external landmark for the aortic bifurcation is generally the umbilicus, although this can vary with age and body habitus. The L4-L5 disk space is generally located near the aortic bifurcation [see Figure 1]. The L4-L5 disk lies in a plane that is generally axial but may be angulated in a slightly caudal direction. In a thin person, the step-off between L5 and S1 can be palpated and identifies the L5-S1 disk space. In the supine patient, the L5-S1 disk lies roughly halfway between the umbilicus and the pubis. However, the L5-S1 disk space is often angulated

Figure 1 (a) The important anatomic relations of the disk spaces to the aorta, vena cava, and iliac arteries and veins are depicted. (b to d) The three differing patterns of venous tributaries into the left common iliac vein are demonstrated. IVC = inferior vena cava.

in a more caudally directed plane than L4-L5. These are all important aspects to keep in mind when planning the surgical approach.

The vascular manipulations necessary during exposures of the lumbar spine are the most critical aspects of the exposure. Exposure at L4-L5 generally involves mobilization of the left common iliac artery and vein. The disk space may be exposed above the vessels, between the vessels, or below the vessels

[see Figure 2]. Chiriano and colleagues reviewed 243 cases of L4-L5 exposure.¹¹ The exposure was achieved superolateral to the left common iliac artery in 44% of cases. Mobilization of the left common iliac artery laterally and left common iliac vein medially was necessary in 45% of cases. The ALV and/or ILV will have to be divided to mobilize the vein medially. In 11% of cases, the exposure was achieved between left and right common iliac veins as described for L5-S1.¹¹ The

Figure 2 The manipulations necessary to expose the L4-L5 disk space are determined by the relation of the disk space to the iliac vessels. (a) Exposure obtained above the left common iliac artery and vein. (b) Exposure obtained between the left common iliac artery and vein. (c) Exposure obtained below the left common iliac vein.

exposure of the L5-S1 disk space is typically obtained between the right and left iliac veins without the need for significant vascular mobilization [see Figure 1]. The median sacral vessels serve as a consistent landmark on the anterior disk surface for the centerpoint of the disk.

Overlying nervous structures within the area of the aortic bifurcation include the sympathetic plexus, which often lies over the origin of the left common iliac artery. Care in this area is important to prevent damage and preserve sexual function, primarily ejaculatory function, in the patient. Also in this area, the ureter must be identified and protected from injury.

CONDUCT OF OPERATION

Anterior approaches are all performed with the patient placed supine on a radiolucent table. Care must be taken to ensure that the patient is not rotated as this will affect the ability to accurately place the instrumentation. The patient's arms are placed on armboards extending out at a 90° angle as arms tucked at the sides will interfere with lateral fluoroscopic imaging. Appropriate monitoring lines are placed by the anesthesia and neurology services. Prior to preparing the operative field, fluoroscopy is performed to identify the levels of interest and mark the level on the skin [see Figure 3]. This simple step avoids malpositioning of the incision and limits

Figure 3 Intraoperative incision planning: (a) fluoroscopy is used to identify the disk space, and (b) the level is marked on the skin.

the size of the incision. The choice of a lower transverse abdominal or vertical paramedian incision typically depends on two factors: the upper level of exposure necessary and the number of levels to be exposed. For exposures involving L4-L5 and/or L5-S1, we prefer a lower abdominal transverse incision. For exposures involving L3-L4 or higher or for all three-level approaches, we prefer a left vertical paramedian incision [see Figure 4]. Both incisions allow for excellent extraperitoneal exposure.

When a transverse incision is made, the incision is generally approximately 3 cm below the umbilicus when the L4-L5 disk is to be exposed. Because of the more caudal angulation of the L5-S1 disk space, isolated L5-S1 exposure can be obtained with a transverse incision a few fingerbreadths above

the pubis. When both L4-L5 and L5-S1 are to be exposed, the incision generally is made slightly favoring the upper level because of the importance of adequate exposure to address vascular manipulations, which are frequently required at L4-L5. The soft tissues are divided with cautery down to the anterior rectus sheath. The sheath is divided transversely, with the lateral aspect extending no further than the lateral aspect of the rectus muscles. The anterior rectus sheath is then mobilized away from the rectus muscles in a cephalad and caudal direction. This will allow lateral retraction of the muscles and superior-inferior retraction of the fascia. The muscle bellies are separated in the midline, and the muscles are mobilized laterally. The midline plane may be somewhat scarred if the patient has had a previous cesarean section

Figure 4 General guideline for planning skin incision.

or hysterectomy, but these muscles can almost always be separated and retracted. The extraperitoneal plane is then developed, with dissection being carried out behind the rectus muscles. The inferior portion of the posterior rectus sheath may be encountered and is divided in a vertical direction to then allow entry into the extraperitoneal plane. In the midline, the peritoneum may be adherent to the linea alba, and careful sharp dissection is necessary. When there has been a previous lower midline or Pfannenstiel incision, the extraperitoneal plane can generally be developed slightly laterally toward the left, away from any scarring. Dissection can then be carried back toward and across the midline. At any point, if a hole is made in the peritoneum, dissection can be carried out in another location and the extraperitoneal plane developed while keeping the peritoneum mostly intact. The dissection proceeds downward and toward the patient's left with mobilization of the peritoneum and its contents toward the right.

When a left paramedian incision is chosen, the dissection begins as above. Once the anterior rectus sheath is identified, the sheath is incised vertically 2 to 3 cm lateral to the midline. The fascia is mobilized away from the left rectus abdominus muscle. The left rectus is then dissected to the midline and mobilized laterally. The posterior rectus sheath is then identified and incised vertically. The extraperitoneal plane is then entered. Given the vertical orientation, this incision allows for more optimal access when three-level exposures are necessary and is favored for any lumbar exposure above L4-L5.

Once the extraperitoneal plane is developed via either the transverse or paramedian approach, dissection is generally unencumbered downward and to the patient's left [see Figure 5]. Care should be taken to avoid injury to the inferior epigastric vessels, which should be left anteriorly attached to the posterior aspect of the rectus. The round ligament may be identified and divided during this portion of the procedure. In males, the spermatic cord is mobilized and retracted inferomedially. The psoas muscle can be identified at this point.

Blunt dissection is used to mobilize the peritoneal contents medially while keeping the peritoneum intact. Cephalad dissection in a retronephric plane will allow creation of a larger dissection space. The ureter is identified and rotated medially along with the peritoneal structures. The external iliac artery will be seen and can be traced to the left common iliac artery and the aorta. This dissection anterior to the arteries can be done bluntly, but there may be some small veins coursing anteriorly that can be cauterized. The distal dissection typically then occurs medial to the iliac vessels. Occasionally, the obliterated umbilical artery (a branch of the internal iliac artery) will be encountered and should be ligated and divided. The bladder is typically caudal to the area of dissection and is not directly identified. At this point, a self-retaining retractor system is essential. We prefer the Omni-Tract surgical retractor system (St. Paul, MN) with radiolucent blades. This allows the maintenance of exposure throughout the instrumentation process with minimal interference.

Often multilevel exposures are required, and exposure of the disk spaces usually proceeds in a cephalad to caudal direction. When multiple disk levels need to be treated, it is safer to expose one level at a time. Adequate exposure often

requires retraction of the vessels, and optimal exposure of one level may compromise the exposure of the other disk levels. The dissection at each level should be carried out sequentially. After one level has been adequately exposed, the retractors can then be adjusted to expose the subsequent (typically more caudal) level. For proper instrumentation to take place, wide exposure of the anterior aspect of the intervertebral disk must be achieved. The placement of an artificial disk requires clear identification of the midline of the disk and extensive side-to-side exposure of the anterior aspect of the disk. The performance of fusion with anterior instrumentation typically involves less side-to-side exposure of the disk but does require exposure of several millimeters of the vertebral bodies adjacent to the disk. Thus, it is important for the exposure surgeon to be aware of the surgical plan.

The most common intervertebral disk levels that require exposure are the L4-L5 and the L5-S1 disks. The L4-L5 disk level will often be more difficult to expose. The key intraoperative decision is what relation the disk space holds to the iliac vessels [see Figure 2]. This can often be anticipated in light of preoperative imaging (when available). Palpation of the disk will often clearly identify the important relations determining whether the window should be created above the left common iliac artery, between the left common iliac artery and vein, or below the left common iliac vein. During all manipulations of the left common iliac vein, careful dissection and control of the ilio-lumbar and ascending lumbar veins are key.

For exposure of the L5-S1 disk, the sacral promontory can be easily palpated in the retroperitoneal space. Dissection is carried out medially to the left common iliac vessels. The left common iliac vein can generally be carefully retracted laterally, and the soft tissues over the L5-S1 disk can be divided. The middle sacral artery will be identified and serves as an excellent mark for the midline of the disk. The middle sacral artery and vein can be divided with ligature, the harmonic scalpel, electrocautery, or clips. Blunt dissection can then be used to retract the tissues toward the right, medial to the right common iliac vein, and complete the exposure of the anterior aspect of the disk.

Once all levels have been exposed, radiopaque markers are placed in the disk spaces. This allows confirmation of the appropriate level by the exposure surgeon and confirmation by the spine surgeon [see Figure 6]. By obtaining anteroposterior and lateral views, this also allows the identification of the centerline, which is very important during instrumentation.

Instrumentation is then performed by the spinal surgeon. Clearly orienting the spinal surgeon about the relevant anatomy, retractor positioning, and centerline will help avoid any potential for injury. As a result of the observation that nearly all serious vascular injuries occur during the instrumentation portion of the procedure, we have adopted the policy of remaining scrubbed and assisting with the instrumentation. Often at L4-L5, compression of vascular structures is necessary to obtain adequate exposure [see Figure 7]. Periodic relief of compressing retractors will help avoid any thrombotic complications. Compression of vascular structures is rarely necessary at L5-S1 [see Figure 8]. Following completion of instrumentation at each level, the retractors should be readjusted to optimize exposure.

Figure 5 The avascular retroperitoneal plane is developed by blunt dissection. Initial dissection may be carried out lateral to the rectus muscle, but once retractors are placed, lateral retraction of the left rectus is performed to facilitate midline exposure of the disk space.

After completion of the spine portion of the procedure, hemostasis is initially confirmed with the retractors in place. Careful removal of the individual retractor blades is necessary to inspect for hemostasis as a retractor blade may have provided a tamponade effect on a venous injury. To aid in hemostasis, we use spray fibrin sealant (Tisseel, Baxter Biosurgery, Deerfield, IL). The myofascial layers are reconstructed in a layered fashion.

The exposure of the L2-L4 disks is relatively simple because major veins will not need to be mobilized. A left-sided, vertical paramedian incision is useful for this exposure. At higher levels (L2-L3), the genitofemoral nerve can be identified on the anterior aspect of the psoas muscle and should be left in

situ. The aorta can then be mobilized medially off the spine. Lumbar arteries and veins need to be divided on the left side to gain full anterior exposure of the spine. It is important to ligate the lumbar veins prior to retraction, or these veins can be avulsed off the vena cava, and this will result in hemorrhage that is difficult to control. Care must be taken when there is atherosclerotic disease in the aorta. If the aorta is calcified, injuries can occur with retraction as it is often necessary to retract the aorta at a fairly acute angle to obtain exposure of the spine at these levels.

Once the procedure is completed, it is essential to perform a pulse examination of the lower extremities. Early detection of arterial occlusions is crucial for the best possible outcomes.

Figure 6 Intraoperative fluoroscopy is used to confirm the appropriate level and to identify the midline. (a) The anteroposterior view demonstrates the radiopaque markers in the L4-L5 and L5-S1 disk spaces. The relation of the marker to the spinal process helps determine the midline. (b) A lateral view clearly confirms the disk levels. (Note that the radiolucent retractor blades can be left in place during imaging.)

Figure 7 The exposure obtained at L4-L5 often requires extensive mobilization of the left iliac vessels. (a) Extensive side-to-side exposure is generally necessary for placement of the artificial disk. (b) Periodic relaxation of the retraction during preparation of the disk space is suggested.

Figure 8 The exposure obtained at L5-S1 rarely requires vascular manipulations. (Note that the middle sacral vessels have been divided.)

Again, it is incumbent on the exposure surgeon to have an accurate assessment of the preoperative pulse examination to identify significant changes. In our practice, we have not found pedal pulse oximetry probes or somatosensory evoked potentials to be of use in identifying arterial injuries.

Postoperative Care

The patients should have neurovascular checks postoperatively. If the peritoneum is entered, the patient may experience a transient ileus. Most patients can be started on a clear liquid diet on postoperative day 1 and advanced as tolerated. Patients with multilevel reconstructions and those with paramedian incisions tend to have a more prolonged ileus than patients who undergo single-level exposures, but this is unpredictable. Depending on the number of levels treated and method of instrumentation, the patient may be in a soft corset or rigid spinal brace postoperatively. Early mobilization is encouraged, and the patients are often ambulating with the physical therapists on the first postoperative day.

Pain control is often a major issue in the perioperative period. Many patients will be on a significant amount of oral analgesia preoperatively, and this should be considered when attempting to control postoperative pain. Consultation from a pain specialist is often helpful in the management of patients on chronic narcotics. Patients will experience pain not only from the anterior incision but also from the instrumentation of the spine. The Foley catheter should be removed as soon as possible. Prophylaxis against venous thromboembolic disease should be continued until the patient is able to ambulate well.

Complications

VASCULAR INJURIES

During the exposure of the intervertebral disk spaces, mobilization of the iliac veins and sometimes mobilization of the iliac arteries are necessary. Injuries to these vessels can

occur during this mobilization or during the spinal instrumentation. Arterial injury is rare. When calcified atherosclerosis is present in the iliac arteries, associated plaque can be injured during retraction. This can lead to bleeding or thrombosis. Tears are usually amenable to primary suture repair; arterial reconstruction is rarely necessary. Vessel thrombosis is also rare but amenable to repair using standard vascular techniques. Castro and colleagues described a case of distal aortic thrombosis after spinal surgery.¹² Bilateral iliofemoral thrombectomies were performed, but, ultimately, the patient expired following bilateral amputations. Raskas and Delamater described thrombosis of the left iliac artery in a patient with calcified atherosclerosis of the aorta.¹³ This injury required bypass of the artery with a Dacron graft.

Venous injuries are usually minor; however, the lack of exposure can make control of these injuries difficult. Simple suture repair of the venous injuries can frequently control the bleeding and fix simple injuries. Often major venous injuries occur as a result of attempts to repair smaller injuries. This can occur during attempts to clamp the vein or when there is an unsuccessful attempt at suture repair. The iliac veins can be controlled by proximal and distal compression without full mobilization of the veins, which allows direct suture repair and avoids collateral injuries.

Hamden and colleagues reviewed their experience of 480 patients who had anterior exposure of the spine.¹⁴ Vascular injuries occurred in 11% (54 of 480) of patients. Only two injuries were arterial. The majority of the injuries were venous, with the left common iliac vein being most frequently injured. Only 1.9% of the injuries were severe, which was defined as injuries that required blood transfusion or vascular reconstruction or resulted in greater than 300 cc of blood loss. As suggested previously, the L4-L5 level was associated with more vascular injuries.

In our experience with 405 anterior exposures, several trends have been identified in vascular injuries.¹¹ Minor injuries to venous structures requiring simple repair with monofilament suture occur in nearly one quarter of cases and are more common when L4-L5 exposure is performed. These injuries are easily repaired and of minimal consequence and occur when the exposure surgeon is establishing the initial exposure. Major vascular injuries occurred in 3% of cases, with two arterial and 10 venous injuries. All major vascular injuries occurred during the instrumentation portion of the procedure. This observation suggests that the exposure surgeon should remain present and participate throughout the entire procedure and not merely for the opening and closure.

DEEP VEIN THROMBOSIS

Although the iliac veins are commonly manipulated and retracted during anterior spine exposures, deep vein thrombosis (DVT) is rare. Although direct manipulation is felt to play a role in the development of DVT in these cases, other factors are clearly at play, as in all types of major operative procedures. Of three episodes of DVT in our experience, two were associated with a major ipsilateral venous injury, whereas one had no identified injury.¹¹ An episode of DVT following anterior exposure was reported in the setting of a retroperitoneal hematoma that caused compression of the inferior vena cava.¹⁵ Pulmonary embolus is also a rare occurrence,

with Brewster and colleagues reporting one case of pulmonary embolism in their series of 128 cases of anterior retroperitoneal exposure of the lumbar spine.¹⁶ Appropriate perioperative thromboembolic prophylaxis is important in these patients.

LYMPHOCELES

Lymphoceles are rare complications after anterior spinal exposures. The lymphatics are generally either cauterized or, in the case of larger identified lymphatics near the left common iliac artery origin, ligated. There are only a few cases of this complication in the literature following this procedure. If the lymphoceles are large and symptomatic, they may have to be drained surgically. If the symptoms are minimal, conservative management can be attempted.¹⁷

NERVE DYSFUNCTION

The lumbar sympathetic nerves lie lateral to the spine and may be injured during the dissection or from retraction when the spine is exposed. Injury to the sympathetic nerves results in vasodilation of the left lower extremity. Because most exposures approach from the left side, the observation is often made that the right foot is cool. Examination will demonstrate palpable pulses bilaterally, and, in fact, it is the left foot that is abnormally warm from the sympathectomy, whereas the right foot is cool as a result of normal sympathetic tone. This tends to be a self-limiting process with no long-term sequelae.

Of more concern to the surgeons and patients is the potential for sexual dysfunction following anterior spinal surgery. Sexual dysfunction can occur in males (usually retrograde ejaculation as opposed to impotence) as a result of disruption of the intermesenteric nerve plexus and superior hypogastric nerve plexus that course over the left common iliac artery origin.^{18–21} The incidence of retrograde ejaculation after anterior fusion ranges from 0.5 to 6%. With a retroperitoneal approach, the incidence appears to be less than 1%, and half of the cases are temporary.²² The transperitoneal approach appears to have a much greater incidence of retrograde ejaculation, presumably because of the division of the tissues overlying the left common iliac vessels without identification and sparing of the nerve fibers. With the retroperitoneal approach, the tissues overlying the left iliac vessels are generally kept intact and swept with the peritoneal contents toward the right. Although the intermesenteric and superior hypogastric nerve plexuses have bilateral innervations, redo exposures from the right side in a patient with a previous left-sided approach markedly increase the risk of retrograde ejaculation.

BOWEL AND GENITOURINARY INJURIES

Bowel injuries are rare and can be avoided by keeping the peritoneum intact. In our series, one bowel injury occurred during disk removal when the bowel moved into the surgical field through a small defect in the peritoneum.¹⁹ The bowel injuries may be repaired primarily, but as in any case with bowel violation, the potential for hardware infection must be recognized.

The left ureter can be injured during the dissection or mobilization. If there has been previous surgery in this area,

a ureteral stent can be considered. Gumbs and colleagues reported a ureteral injury that was repaired by a urologist intraoperatively.²³ Interestingly, this injury occurred in a patient who had a stent placed preoperatively. Again, this is a rare complication but needs to be distinguished from a lymphocele. If a urinary leak is discovered postoperatively, urologic evaluation is necessary.²³

RARE INJURIES

There are a variety of other rarely reported complications related to the anterior retroperitoneal spine exposure. The incidence of incisional hernias is quite low (zero in our experience) but may be a source of chronic postoperative discomfort. Other rarely reported complications include postoperative pancreatitis and the development of retroperitoneal fibrosis.

Exposure Options

The goal of the anterior retroperitoneal spine exposure is to gain the best access to the spine to optimally perform the spinal procedure. There are three main approaches to this: the conventional exposure, the mini-open muscle-splitting exposure, and the laparoscopic approach. All three techniques involve the same dissection of the pelvic vasculature. The main difference is the skin incision, violation of the peritoneum, and the approach to the myofascial layers.

CONVENTIONAL RETROPERITONEAL APPROACH

The conventional anterior retroperitoneal approach is our preferred approach, as described in detail above. Although the incision typically ranges from 10 to 15 cm in length, the exposure attained is excellent. The iliac vessels can be carefully mobilized and protected as the exposure allows for adequate access. In the case of vascular injuries, no further extension of the exposure is necessary. As a bonus, the cosmetic results appear quite good with the standard transverse incision.

MINI-OPEN APPROACH

Brau has described his mini-open approach for exposure of the L3-L4, L4-L5, and L5-S1 levels.²⁴ For a single level, a small transverse incision on the left side of the abdomen is performed. For multiple levels, an oblique incision is performed. The spinal levels to be exposed determine the position of the incision. The anterior rectus sheath is incised, and the left rectus muscle is circumferentially mobilized, allowing medial and lateral retraction. The retroperitoneal space can then be entered. The iliac vessels are then mobilized. The technique allows for a smaller incision than the standard transverse or paramedian incisions, but the exposure is admittedly limited. Compression of the iliac vessels is common as a result of the limited exposure. Brau acknowledges that this technique cannot be used in all patients. When used, an incision of 6 to 10 cm for single-level exposures and 8 to 18 cm for multilevel exposures is possible. The length of the incision and the ease of exposure vary with the patient's body habitus. Obviously, a thinner patient's lumbar spine can be easily exposed with a smaller incision.

LAPAROSCOPIC APPROACH

Laparoscopic anterior spinal exposure was first described in 1995 by Zuckerman and colleagues.²⁵ The laparoscopic approach for the L5-S1 levels can be relatively straightforward. Given that the only vessels that need to be divided are the middle sacral vessels, this can be achieved in most cases using a laparoscopic approach. There is extensive experience in the literature that shows that the laparoscopic approach to L5-S1 disk level is effective.^{26–33} The exposure of the L4-L5 level can be more challenging. Kleeman and colleagues described their experience using laparoscopy to expose the L4-L5 disk level.²⁸ They were successful in 135 of 139 cases. All of their failures were in the first 30 cases, which demonstrates that this approach has a significant learning curve. Their experience mobilizing the iliac arteries and veins was very similar to standard open techniques. All methods of vein mobilization that Chiriano and colleagues described were necessary using the laparoscopic approach.¹¹ Kleeman and colleagues used preoperative CT or MRI to determine the venous anatomy and therefore aid in planning the laparoscopic approach.²⁸ They also experienced the vascular complications that are seen with open surgery, including arterial embolization, venous bleeding, and DVT.

TRANSPERITONEAL APPROACH

A standard, transperitoneal open approach to the lumbar spine has been described. In general, the approach may use a lower midline or transverse incision. Instead of dissection proceeding in an extraperitoneal plane, the peritoneum is entered and the bowel is packed. The retroperitoneum is then entered, and the disk spaces are exposed. This dissection has the drawback of bowel manipulation and has been shown to have a markedly elevated incidence of retrograde ejaculation.²² We have reserved this approach for remedial operations following previous anterior retroperitoneal approaches when the removal of hardware is necessary.

COMPARISON OF APPROACH OPTIONS

Kaiser and colleagues compared their experience using the mini-open and laparoscopic approaches.²⁷ Operative times were longer with the laparoscopic approach. In the mini-open group, the hospital stay was marginally longer, but this was statistically significant. The complication rate was higher in the mini-open group; however, this was driven by the occurrence of mild ileus. Importantly, the incidence of retrograde ejaculation was significantly higher in the laparoscopic group—a finding supported by others.²²

Zdeblick and David compared mini-open and laparoscopic approaches.²⁹ They found no difference between the two groups when a single disk level was exposed. In contrast, when more than one level was exposed, the operative time and complication rates were higher with the laparoscopic approach. Most importantly, inadequate exposure was seen in 16% of patients. This led to only a single cage being placed, which may compromise the long-term results of the procedure. The mini-open group had no patients with inadequate exposure.

When considering all of the approaches, the surgeon must take into account the primary goal of the spine surgeon. The

incision length, approach, and risks should be explained to the patient at the initial evaluation as informed consent regarding the exposure is the responsibility of the exposure surgeon. Personal preference often plays a role, but the virtues of the various approaches should be understood. In our experience with the retroperitoneal approach, we have always been able to accomplish the exposure safely and allow for the optimal placement of instrumentation.

Special Considerations

REPEAT ANTERIOR EXPOSURE

If the patient has had previous surgery via the anterior or posterior approach, the dissection will be more difficult as a result of scarring in the operative field. Infections of previous instrumentation of the spine can also make the dissection more treacherous. For redo operations, different approaches should be considered. If there was a previous exposure via the left retroperitoneal approach, the redo operation via the right retroperitoneal approach may be considered for L5-S1. When the retroperitoneum is too scarred for development of a dissection plane, a transperitoneal approach can be used, but the risk of retrograde ejaculation may be higher.^{19,22} Previous left colon surgery often leads to extensive inflammation in the area of L4-L5 and should be considered a contraindication for anterior exposure. The previous performance of a hysterectomy or cesarean section has not prevented successful anterior retroperitoneal exposure in our experience.

Placement of a prosthetic polytetrafluoroethylene patch around the iliac vessels at the time of initial spinal instrumentation has been suggested as an aid for redo procedures. In theory, this should provide a plane of repeat dissection between the instrumentation and the patch while protecting the vessels. Although this sounds appealing, the utility of this is unknown. Given the high risk of repeat anterior approaches, other alternatives should be sought. For removal of infected instrumentation at L4-L5, we have employed a lateral approach to lessen the risk of vascular injury.

THORACOLUMBAR EXPOSURE FOR SPINAL FRACTURE

Exposure of the distal thoracic and proximal lumbar spine (T12-L2) is often necessary in the setting of trauma. T12-L1 pathology is most often a result of blunt trauma. These patients present all of the challenges of a trauma patient. The surgeon performing the exposure will often have more experience dealing with trauma patients; therefore, it is that surgeon's responsibility to ensure that the patient is stable enough to undergo the procedure. These patients will often have concomitant chest trauma, the left chest may be entered, and there may be some compromise of pulmonary function. The fracture site can often bleed significantly intraoperatively, and it is essential that blood products are available.

The patient is placed in the lateral decubitus position using a bean bag. Fluoroscopy is used to identify the fracture and plan the incision. A left thoracoabdominal incision over the ninth, 10th, or 11th rib typically allows exposure of the T11 through L1 vertebral bodies. The myofascial layers are incised, including the serratus anterior and the latissimus dorsi muscles. This will expose the rib, and the dissection is carried out with care to avoid injuring the neurovascular

bundle. Harvest of the rib for use as a bone graft can be performed at this point. Care should be used to avoid entry into the pleural space. If violation of the pleura occurs, a chest tube should be placed at the completion of the procedure. The external and internal oblique muscles are then divided, followed by the transversalis layer, and the retroperitoneal space is entered. The dissection is carried in the retronephric plane, and the peritoneal contents are mobilized anteriorly with complete dissection off the undersurface of the diaphragm. Care must be taken when performing this dissection to avoid injury to the spleen. The crus of the diaphragm may be incised to gain access to the spine. With division of the crus, the pleural space may again be entered.

When treating spinal fractures, the exposure needs to provide access to the vertebral body above and below the fractured vertebra to allow for instrumentation. Typically, the body of T12 can be reached by mobilizing the left crus of the diaphragm from the retroperitoneum. The thoracic cavity may be entered cephalad to the diaphragm if more superior exposure is necessary, as is typical for the T11 level. In this case, dissection can be carried out above and below the diaphragm without division of the diaphragm. The lateral aspect of the vertebral bodies can then be obtained by lateral retraction of the psoas muscle. Segmental vessels are frequently encountered and require division with ligation or cautery. Exposure of the spine at these levels for adequate

decompression and fixation typically requires a lateral approach, and the anterior portion of the vertebral body is not exposed. The level is then confirmed fluoroscopically, and the instrumentation is then performed. Once the spine is treated, the crus and the diaphragm will be repaired. A chest tube can be placed, or the pleural cavity can be aspirated as the closure is performed.³⁴ The fascia is then closed in layers.

Improving Resident Training

The increasing use of laparoscopic and endovascular procedures has made open surgery less common than in the past. As endovascular aneurysm repair has become widespread, surgery trainees have less experience with exposure of the aorta and iliac vessels. Anterior retroperitoneal spine exposure offers an opportunity to increase the experience of surgeons in training in open surgery. This applies not just to vascular trainees but also those in general surgery, urology, and gynecology who may all benefit from this experience. Trauma surgeons may infrequently encounter difficult pelvic venous injuries, and experience in elective treatment in a nonstressful environment will add to more confidence. All of this experience can be gained while ensuring patient safety in the performance of anterior spine exposures.

34 AORTIC DISSECTION

Mark F. Conrad, MD, MMSc, and Richard P. Cambria, MD

Acute aortic dissection is the most common catastrophic event affecting the aorta. However, its overall prevalence is rare, occurring in three of every 1,000 patients who present to the emergency department with chest and/or back pain.¹ Acute aortic dissection is a lethal disease: early studies showed that in the absence of treatment, the majority of patients died within 3 months of presentation. Reported mortality rates of untreated patients approached 75% within the first 2 weeks after the onset of symptoms.² Few survived the chronic phase more than 5 years as a result of progressive aneurysmal degeneration and rupture of the outer wall of the false lumen.^{3,4} Despite improvements in both medical and surgical therapies, overall mortality associated with acute dissection in contemporary practice remains significant: mortality was 27% in a recent report from the International Registry of Acute Aortic Dissections (IRAD).⁵ Early death attributable to an acute dissection of the ascending aorta is usually secondary to the central cardioaortic complications of aortic rupture into the pericardium, acute aortic regurgitation, and coronary ostia compromise,^{6,7} whereas descending aortic dissections are more commonly associated with death from end-organ compromise attributable to visceral or extremity malperfusion.^{8,9}

General Features

CLASSIFICATION

Aortic dissections are classified according to the anatomic location of the entry tear and the time between onset of symptoms and patient presentation. A dissection is considered acute when the diagnosis is made within 2 weeks of the initial onset of symptoms and thereafter becomes chronic. Although such a designation appears arbitrary, it is based on autopsy studies that showed that 74% of patients who die from aortic dissections do so in the first 14 days.¹⁰

Anatomically, aortic dissection is classified based on the location of the intimal tear and the extent of the dissection along the aorta. Two classification schemes are used to describe aortic dissections. The DeBakey classification delineates both the origin of the entry tear and the extent of the descending aortic dissection as follows [see Figure 1].¹¹

- Type I: dissection originates in the ascending aorta and extends through the aortic arch and into the descending aorta and/or abdominal aorta for a varying distance
- Type II: dissection originates in and is confined to the ascending aorta
- Type IIIa: dissection originates in the descending aorta and is limited to the same
- Type IIIb: dissection involves descending and variable extents of the abdominal aorta

The Stanford classification simplified the anatomic classification according to the origin of the entry tear alone. A

Stanford type A dissection originates in the ascending aorta and therefore encompasses DeBakey type I and II dissections, whereas a Stanford type B dissection originates in the descending aorta distal to the origin of the left subclavian artery and includes DeBakey types IIIa and IIIb [see Figure 1].

INCIDENCE AND EPIDEMIOLOGY

Recent population-based studies have estimated the incidence of acute aortic dissection to range from 2.9 to 3.5 per 100,000 person-years.^{12,13} Men are more frequently affected, with a male-to-female ratio of 4:1 reported in a recent IRAD series.¹⁴ In our cumulative experience, type A dissections account for 60% of cases, and this is consistent with the IRAD data, wherein 62.5% of 1,417 patients presented with a type A dissection.¹⁵ The incidence of type A dissection peaks between 50 and 60 years of age, whereas type B dissections occur more frequently in older patients, between 60 and 70 years of age.⁵

Hypertension is common and was present in 70% of patients in the IRAD database [see Table 1].¹⁴ Aortic wall structural abnormalities and the presence of a bicuspid aortic valve with or without its accompanying aortic root dilatation are well-established risk factors for ascending aortic dissections. Indeed, the presence of a bicuspid aortic valve has been documented in 7 to 14% of all aortic dissections.^{5,16} Other aortic diseases, such as coarctation of the aorta, annuloaortic ectasia, chromosomal abnormalities (Turner syndrome, and Noonan syndrome), aortic arch hypoplasia, and hereditary conditions (Marfan syndrome and Ehlers-Danlos syndrome), are also risk factors for the development of acute aortic dissection.¹⁷ Marfan syndrome accounts for 50% of cases of acute aortic dissection in patients under 40 years of age.¹⁴

It has been previously reported that in women under 40 years of age, 13 to 50% of aortic dissections occur during pregnancy.^{14,18} Preeclampsia with resultant hypertension is the most common etiology of peripartum aortic dissection, but pregnant women with Marfan syndrome are also at high risk. The presence of a dilated aortic root (>4 cm) is the best predictor of dissection in the pregnant patient with Marfan syndrome.¹⁹ Cocaine ingestion is a rare cause of acute aortic dissection in otherwise healthy individuals, with an incidence as high as 37% in an urban setting but less than 1% in the IRAD population.^{14,20,21} These patients are typically young (average age 47 years), male (75%), and smokers (100%) with a history of hypertension (70%) and no particular trend toward dissection type.²¹

Pathologic Anatomy

INTIMAL TEAR

The process of aortic dissection is dynamic and can occur anywhere along the course of the aorta, resulting in a wide

Financial disclosure information is located at the end of this chapter before the references.

Figure 1 Acute aortic dissection can be classified by the original DeBakey system (*black*) based on the location of the proximal tear and distal extent of the dissection flap or by the Stanford system (*red*), which uses the location of the proximal tear alone.

spectrum of clinical manifestations. The pathognomonic lesion is one of an intimal tear followed by blood surging either antegrade (typically) or retrograde (depending on the hemodynamic gradient between the true and false lumina) and cleaving the intima and media layers of the aortic wall longitudinally for a variable distance.^{22,23} The typical tear is transverse, not circumferential, but the intimomedial layer can be cleaved both longitudinally and circumferentially.²² The adventitially bound, blood-filled space created between the dissected layers of the aortic wall becomes the false

lumen. Fenestrations (connections between the true and false lumina) occur within the intimal flap downstream, usually at branch vessel ostia, which are cleaved by the dissection process: these serve as sites of reentry of blood flow into the true lumen, thus maintaining false lumen patency. The presence of an “intimal flap,” representing the intimomedial septum between the true and false lumen, is the most characteristic pathology in acute aortic dissection. The origin of the intimal flap or tear is in the ascending aorta in 65%, in the descending aorta in 25%, and in the arch or abdominal

Table 1 Demographic and Clinical Features of Combined MGH and IRAD Experience with Acute Aortic Dissection			
Variable	MGH, n (%) ⁸	IRAD, n (%) ²⁷	Total, n (%)
Patients	512	1078	1590
Age, yr (mean)	62	62.4	
Male	347 (67.8)	732 (67.9)	1,079 (67.9)
Type A	278 (54)	674 (62.6)	952 (60)
Hypertension	361 (70.5)	755 (71.8)	1,116 (70.2)
VC/pulse deficit	159 (31)	259 (27.7)	418 (26.3)

IRAD = International Registry of Acute Aortic Dissections; MGH = Massachusetts General Hospital; VC = vascular complication.

aorta in 10% of patients.⁵ In the descending aorta, the intimal tear typically originates within a few centimeters of the left subclavian artery because this segment of the aorta is subject to the greatest fluctuations in left ventricular pressure.^{2,10,24} In the usual pattern of a Stanford type B dissection, the cleavage plane will progress with the distal false lumen on the left posterolateral aspect of the aorta (80% of patients); the celiac, superior mesenteric, and right renal arteries typically emanate from the true lumen, and the left renal artery arises from the false lumen [see Figure 2].¹⁰ It is to be emphasized, however, that variations in this pattern are frequently encountered.

ASSOCIATED PROCESSES

One pathologic process that is associated with increased risk of aortic dissection is medial degeneration of the aortic wall (cystic medial necrosis) that diminishes the structural integrity (collagen and elastin fibers) of the aortic layers.²⁴⁻²⁶ This process appears to be an essential feature of several hereditary conditions, such as Ehlers-Danlos syndrome and Marfan syndrome.¹⁷ Although specific connective tissue diseases account for only 10 to 15% of all acute aortic dissections, the degree of medial degeneration in otherwise normal patients with aortic dissection is greater than that of age-matched controls.⁵ Atherosclerosis has not been

Figure 2 Computed tomographic angiogram findings of acute aortic dissection. (a) Axial image of aortic dissection with the superior mesenteric artery arising from the true lumen (*black arrow*). (b) Axial image of aortic dissection with the right renal artery (*red arrow*) arising from the compressed true lumen. (c) Axial image of aortic dissection with the left renal artery originating from the false lumen. (d) Axial image of aortic dissection with compressed true lumen (*thick arrow*). FL = false lumen.

considered to be an important etiologic feature of acute aortic dissection and was present in only 31% of patients in the IRAD.²⁷ However, Jex and colleagues noted either gross or microscopic atheroma in 83% of patients in their series.²⁸ The presence of an atherosclerotic aneurysm presenting with concurrent aortic dissection is uncommon, occurring in only 14 to 15% of patients in recent series.^{27,29} The unusual coexistence of an aortic dissection that originates in and/or involves a preexistent atherosclerotic aneurysm appears to change the natural history; rupture is the likely scenario. To wit, in a review of 325 patients with aortic dissection, rupture in the abdomen occurred only in the setting of antecedent degenerative, atherosclerotic aneurysm.³⁰ These findings support the posture of treating such type B dissections as “complicated,” and initial surgical priority should be given to the aorta where both entities are present (usually the infrarenal abdominal aorta).

Malperfusion Syndromes

Malperfusion syndrome occurs when there is end-organ ischemia secondary to aortic branch compromise from the dissecting process. This can involve one or more vascular beds simultaneously. Early symptoms are often subtle and of varying severity over the hours and days after the initial onset of symptoms. Consistent over several series, aortic branch compromise is present in up to 31% of patients with acute aortic dissection,^{9,27,31,32} with progression to the malperfusion syndrome correlating with early mortality.^{8,9,27} Virtually any aortic branch can be affected, and as intuitively suspected, the morbid clinical events will vary as a function of the vascular territory involved.

Identifying the mechanisms of branch compromise is a critical step in formulating effective treatment plans. The anatomic and physiologic variables underpinning any compromised vascular bed include (1) the percentage of aortic circumference dissected, (2) the presence of a distal reentrant focus in the false lumen or true lumen outflow, and (3) the topography of branch ostia to the true versus the false lumen.⁶ In the minutes after an aortic dissection is initiated, the true lumen (representing the remnant of the original aortic lumen) collapses to a variable degree and the false lumen expands.³³ The adventitially bound outer wall of the false lumen must expand to a larger diameter to accommodate the same wall tension at a given blood pressure, as governed by the law of LaPlace. In contrast, the true lumen, which contains the majority of the elastic components of the aortic wall, undergoes radial elastic collapse.³³ Therefore, the degree to which the true lumen recoils and the false lumen expands (i.e., their respective cross-sectional area) is dependent on the percentage of the total aortic circumference involved with the dissection. In the presence of a deep proximal tear and the absence of distal fenestrations, the mean false lumen pressure increases, leading to compression of the true lumen³⁴ [see Figure 2]. A compressed true lumen will lead to impaired perfusion of distal structures and should increase the index of suspicion for visceral and renal ischemia. Two mechanisms for aortic branch vessel compromise have been identified, each of which has specific treatment implications in the management of malperfusion syndromes.³³

DYNAMIC OBSTRUCTION

In dynamic obstruction, the dissection flap prolapses into the vessel ostium and impedes blood flow with each cardiac cycle [see Figure 3]. This is the more common mechanism of branch compromise and is responsible at least in part for some 80% of malperfusion syndromes.³⁵ The severity of the true lumen collapse and the degree of aortic-level ostial vessel occlusion are determined by the circumference of the dissected aorta, cardiac output, blood pressure, heart rate, and peripheral resistance of the outflow vessel.³⁶ Pulse deficits based on dynamic obstruction may wax and wane over time because of variability in the aforementioned

Figure 3 Mechanisms of aortic branch obstruction in acute dissection. (a and b) In dynamic obstruction, the septum may prolapse into the vessel ostium during the cardiac cycle, and the compressed true lumen flow is inadequate to perfuse branch vessel ostia, which remain anatomically intact. (c, d, and e) Near-complete circumferential dissection with static obstruction; the cleavage plane of the dissection extends into the ostium and compromises inflow. Thrombosis beyond the compromised ostia may further worsen perfusion.

factors.^{6,37} Chung and colleagues modeled the anatomy and physiologic conditions of a Stanford type B aortic dissection in vitro and concluded that the movement of the dissection flap to produce dynamic obstruction of any branch vessel is related to the size of the entry tear, the limitation of false lumen outflow, and increased true lumen outflow produced by falling peripheral resistance.³⁶

STATIC OBSTRUCTION

In acute dissection, the false lumen is highly thrombogenic as a result of the exposed adventitial and medial layers. Thrombus formation may occur in the blind end of the dissection column; more often, “reentrant” foci maintain false lumen flow.³⁸ If the blind end or the propagating end of the dissection column enters and constricts the ostia of a branch vessel, organ injury can occur by thrombosis or hypoperfusion of the involved vessel. This mechanism for malperfusion syndrome involves the dissecting process extending into the branch vessel proper, narrowing it to a variable degree, and has been termed *static obstruction*.³⁵ This obstruction is unlikely to resolve with restoration of aortic true lumen flow alone, and some manipulation of the vessel itself (e.g., stent, bypass graft) will typically be required [see Figure 3].

Clinical Presentation

PAIN

The most common presenting symptom of acute aortic dissection is pain (located in the back, abdomen, or chest), reported in over 93% of patients, with 85% specifying an abrupt onset.^{5,39} Whereas the pain is typically described as anterior in location in type A dissections, for type B dissections, pain is more often experienced in the back (78% versus 64%, respectively).^{5,16} The classic presentation of an “acute aortic syndrome” is severe chest or back pain that causes the patient to seek medical attention within minutes to hours of onset and has been described as “the worst ever” by nearly 90% of patients.⁵

HYPERTENSION

On initial physical examination, arterial hypertension is present in 70% of type B dissections but only in 25 to 35% of type A dissections. The presence of hypotension complicating a type B dissection is rare (<5% of patients) but may be present in 25% of dissections that involve the ascending aorta, potentially as a result of aortic valve disruption or cardiac tamponade.⁵ The malperfusion of brachiocephalic arteries by the dissection may falsely depress brachial cuff pressures.⁴⁰ Hypertension that is refractory to medical management is common in type B dissections, occurring in 64% of patients.⁴¹ However, as this refractory hypertension is usually not associated with renal artery compromise or aortic dilatation, continued medical management is warranted.

PERIPHERAL VASCULAR COMPLICATIONS

Peripheral vascular complications are common and occur in 30 to 50% of patients in whom the aortic arch and/or the

thoracoabdominal aorta is involved.^{9,31,32} In patients with peripheral vascular complications not involving the ascending aorta, the brachiocephalic trunk is involved in 15% patients, the common carotid arteries in 20%, the left subclavian artery in 15%, and the iliofemoral arteries in 35%.^{9,42} In this population, mortality is clearly linked to the number of pulse deficits at the time of presentation. Indeed, within the first 24 hours, the mortality increases from 9.4% in patients with no deficits to 35.3% in patients with three or more deficits.⁴² Although it is uncommon for isolated lower extremity pulse deficits to cause mortality as a result of lower extremity ischemia or its sequelae, leg ischemia remains a marker of extensive dissection.⁹

OTHER COMPLICATIONS

Syncope may complicate the presentation of acute aortic dissection in 5 to 10% of patients, and its presence often indicates the development of cardiac tamponade or involvement of the brachiocephalic vessels.⁴³ Overall, patients in the IRAD who presented with syncope were more likely to have a type A dissection than a type B (19% versus 3%, $p < .001$), more likely to have cardiac tamponade (28% versus 8%, $p < .001$), and more likely to die in the hospital (34% versus 23%, $p = .01$).⁴⁴ Spinal cord ischemia from the interruption of intercostal vessels is clearly more common with type B aortic dissections, occurring in 2 to 10% of all patients.⁴⁵ In addition, direct compression of any peripheral nerve can occur, albeit rarely, resulting in paresthesia (lumbosacral plexopathy), hoarseness of voice (compression of recurrent laryngeal nerve), or Horner syndrome (compression of sympathetic ganglion).^{46–48}

Diagnosis

In the United States, acute chest pain is the chief complaint in 8.2% of all emergency department visits. This translates to almost 4.6 million patients annually.⁴⁹ The majority of these patients do not have an aortic dissection, and it would be inefficient, unrealistic, and costly to obtain axial imaging on all patients with acute chest pain. Indeed, the indiscriminate application of thoracic imaging to patients with a low pretest probability of having an aortic dissection has been predicted to yield an 85% false positive rate.⁵⁰ However, aortic dissection often affects younger patients (in their 50s) and thus is often not readily apparent. Indeed, physicians correctly suspect the entity in only 15 to 43% of presentations as aortic dissection is often identified as an incidental finding during evaluation of another pathologic process.^{13,51} A recent review of the IRAD population showed that the average time between presentation and confirmation of the diagnosis was 24 to 34 hours depending on the patient’s age.¹⁴ This underscores the importance of clinical suspicion for early identification, and aortic dissection should be considered in patients who present with persistent chest pain, a normal chest x-ray, and a negative cardiac workup.

IMAGING

The goal of imaging is to first confirm the diagnosis of acute aortic dissection and then determine the extent of dissection, the potential involvement of branch vessels, and the presence of immediate life-threatening complications,

such as tamponade. Historically, retrograde aortography was considered the reference standard in the evaluation of acute aortic dissection. However, the improvement of other techniques, such as contrast computed tomographic angiography (CTA), transesophageal echocardiography (TEE), and magnetic resonance imaging (MRI), has shifted the role of aortography from diagnostic to adjunctive during endovascular management. An evaluation of the IRAD data showed that worldwide from 1996 to 1999, CTA was the initial test performed in 63% of patients and 75% underwent CTA as part of the workup.⁵² TEE was also routinely used (72%), although it was the first test obtained in only 32% of patients. More than two thirds of patients required two or more imaging tests, with MRI (19%) and aortography (19%) used with the same frequency.⁵²

COMPUTED TOMOGRAPHIC ANGIOGRAPHY

CTA has become the test of choice for the identification and characterization of acute aortic dissections. It is readily available and noninvasive and has a reported sensitivity of 83 to 95% and a specificity of 87 to 100% for the diagnosis of acute aortic dissection.^{53–55} The chief limitation of CTA is the ascending aorta, where the sensitivity may drop to less than 80%, but this is readily overcome by the addition of TEE.⁴⁰ A dedicated protocol to image the entire aorta is usually sufficient to provide the necessary diagnostic information. A helical CT dissection protocol will give excellent aortic imaging of the true and false lumina, approximate entry tear sites, and aid in planning intervention. In most cases, the true lumen may be localized by its continuity with an undissected segment of the aorta.⁵⁶ However, in circumferential dissection of the aortic root or when imaging of the aortic arch is omitted, this rule may be difficult to apply. The finding of greatest significance is that in the descending thoracic aorta, the false lumen is larger than the true lumen in over 90% of cases ($p < .05$).⁵⁶ As displayed in Figure 2, a slitlike, compressed true lumen is perhaps the key radiographic finding that should substantially raise the index of suspicion for renal/visceral/lower extremity malperfusion syndrome.

Three-dimensional computed tomographic (CT) scan reconstructions can aid treatment planning, but axial imaging affords the best opportunity to detect topographic relations of the true and false lumina and potential aortic branch compromise. Although it is appropriate to operate on acute type A dissections based on CT findings alone, the IRAD data show that most patients undergo preoperative CT (71%) and TEE (77%) (either preoperative or intraoperative) in circumstances where the clinical and/or laboratory signs dictate the need for urgent revascularization.⁵⁷ In comparison with other modalities, CT scanning is the least operator dependent, provides useful anatomic correlates for surgical and endovascular therapy, and most reliably collects information for follow-up analysis and measurement.

ECHOCARDIOGRAPHY

The sensitivity of TEE has been reported to be as high as 98%, and the specificity ranges from 63 to 96%.^{58–60} The advantages of TEE include wide availability, ease of use, and bedside capability. In addition, TEE possesses the ability to detect entry tear sites, false lumen flow or thrombus,

involvement of the arch or coronary arteries, degrees of aortic valvular regurgitation, and pericardial effusions. The addition of color flow Doppler patterns may decrease false positive results by recognizing differential flow velocities in the true and false lumina.⁶¹ The chief limitation of TEE is the anatomic blind spot in the distal ascending aorta and arch secondary to the air-filled trachea and left mainstem bronchus and inability to document dissection extension beyond the diaphragm.⁶² Despite these shortcomings, TEE can be particularly useful in delineating dissection and relevant surgical pathology in the ascending aorta and therefore is chiefly applied in this territory.⁶³ Moreover, in the unstable patient with a suspected acute dissection in the ascending aorta, TEE may be performed in the operating room to expedite diagnosis and definitive therapy.

OTHER IMAGING

Plain chest radiography is often the first imaging study obtained during the workup of acute chest pain, but the findings of aortic dissection on chest radiography are non-specific and never diagnostic. These include widening of the cardiac or aortic silhouette, displacement of aortic calcifications, and effusions.^{5,16} However, in many cases, the initial chest film is negative. Aortography, although rarely used for diagnosis, has a sensitivity of 86 to 88% and a specificity of 75 to 94% for the diagnosis of thoracic aortic dissection, but false negative angiograms can occur when the false lumen has thrombosed.^{64–67} The aortographic findings considered supportive of a diagnosis of aortic dissection include distortion of the normal contrast column, flow reversal or stasis into a false channel, failure of major branches to fill, and aortic valvular regurgitation.⁶⁶

MRI has an overall sensitivity and specificity for diagnosis of aortic dissection in the range of 95 to 100%.^{52,68,69} MRI can detect the site of the entry tear, the extent of the dissection, potential branch vessel involvement, and differential true versus false lumen flow. The overall sensitivity and specificity for diagnosis of branch vessel involvement are 90% and 96%, respectively.⁷⁰ The chief limitations of MRI include lack of immediate availability, long examination times, and lack of monitoring for critically ill patients. In addition, patients who have had pacemakers, aneurysm clippings, or ocular implants are not candidates for MRI.

Treatment

Optimal treatment of acute dissection is predicated on timely diagnosis and a thorough understanding of the anatomic extent of the pathology. Prompt institution of intravenous antihypertensive medications to lower systemic blood pressure and pulse (dP/dT) is a key element of initial therapy for all patients, with the goal of stabilizing the extent of the dissection, reducing intimal flap mobility, relieving dynamic aortic branch obstruction, and decreasing the risk of rupture. Mortality in the acute phase of a proximal dissection may exceed 1% per hour related to the central cardioaortic complications of tamponade, acute aortic valvular insufficiency, and coronary obstruction. Thus, prompt ascending aortic graft replacement with or without aortic valve repair or replacement is the treatment of choice for the majority of patients with acute type A aortic dissection.

For patients with type B dissections, the catastrophic complication of rupture is uncommon, except in those patients who present with advanced false lumen dilatation or the equivalent of aneurysm formation at the aortic entry site.⁶ Furthermore, in patients with uncomplicated type B dissections, surgical therapy (i.e., graft replacement of the aortic entry tear site) has not demonstrated superiority over medical or interventional therapy for stable patients, whereas those with malperfusion usually require urgent intervention.³⁹

MEDICAL MANAGEMENT

Currently, medical management in an intensive care unit is the initial therapy for virtually all patients with the tentative diagnosis of aortic dissection. The immediate management of acute aortic dissection is directed toward reducing the hemodynamic forces that have initiated and propagated the intimal tear and cleavage of the aortic wall. The goal of medical therapy is to reduce systolic blood pressure and dP/dT and thereby reduce the forces predisposing the dissected aorta to rupture or compromise of branch vessels.⁴⁰ Intravenous antihypertensive therapy should be started in all patients in whom acute aortic dissection is suspected, with the exception of those with hypotension.⁴⁰ For those patients with hypotension in the setting of acute dissection, an expeditious evaluation for tamponade is warranted, but percutaneous pericardiocentesis as a temporizing measure is not advised as it often accelerates bleeding or shock.⁷¹ In contemporary practice, a combination of a beta blocker and a vasodilator is standard medical therapy. In addition, the beta blocker should be initiated before the direct vasodilator (i.e., sodium nitroprusside); otherwise, the reflex sympathetic stimulation from direct vasodilation will stimulate catecholamine release and resultant increases in dP/dT, opposite of the desired effect. Once the patient's blood pressure has been controlled to a systolic of 105 to 120 mm Hg (or a mean of 60 to 70 mm Hg) and the pain has resolved, the patient can be transitioned to oral antihypertensive medications. Patients who are managed medically should be followed with serial surveillance CT scanning because during the first 4 to 7 years after acute aortic dissection, aneurysmal degeneration of the false lumen in the thoracic aorta may develop in 14 to 40% of patients treated with medical therapy alone.^{5,72,73}

OPEN SURGICAL TREATMENT OF TYPE A DISSECTIONS

A complete review of the surgical literature and state-of-the-art management of acute type A dissection is beyond the scope of this chapter. Medical therapy alone has been associated with a 60% in-hospital mortality in type A dissections, and urgent surgical repair is the treatment of choice unless major neurologic deficits or peripheral vascular complications of the dissection pose greater overall risk (i.e., visceral ischemia) than the threat of proximal rupture. However, following repair of the ascending thoracic aorta, 90% of patients who present with type A dissection and peripheral vascular compromise have resolution of their peripheral symptoms without additional vascular procedures.⁷⁴ In addition, patients who present more than 2 days after symptom onset have already survived the initial high-risk period and as many as half can be treated nonoperatively, with a trend toward improved long-term survival compared with those who undergo immediate operative intervention.⁷⁵

The type A dissection arm of the IRAD was recently used to develop a risk model to predict surgical mortality.⁵⁷ The authors reported an in-hospital mortality of 23.9% and identified age over 70 years, previous cardiac surgery, hypotension or shock at presentation, cardiac tamponade, any pulse deficit, and myocardial ischemia as independent predictors of poor outcome.

The anatomic goal of open repair is resection of the aortic intimal tear with graft replacement and reconstruction of the aortic wall layers in the distal anastomosis so as to eliminate false lumen flow [see Figure 4]. Persistent false lumen flow continues in many patients after ascending aortic graft replacement despite liberal use of circulatory arrest and technical adjuncts such as glue aortoplasty.⁷⁶

OPEN SURGICAL TREATMENT OF TYPE B DISSECTIONS

Threatened or actual rupture at the aortic intimal tear in the proximal descending aorta remains, in our view, the only indication for acute open graft replacement in distal dissection. Unless an extensive aneurysm is present, resection should be confined to the proximal descending aorta as mortality and spinal cord ischemia risk increase dramatically with extensive aortic replacement in the setting of an acute dissection.⁷⁷ Although the anatomic goal of central aortic replacement is reconstruction of the aortic wall layers in the distal anastomosis and obliteration of false lumen flow, 25 to 50% of patients with type B aortic dissections who are treated surgically can be expected to have persistent false lumen flow.^{78,79} Central aortic repair is less commonly performed in contemporary practice because of substantial surgical morbidity, the equivalent results of medical therapy in uncomplicated patients, and the variable success in relieving distal malperfusion. The mortality rate for the open repair of acute type B aortic dissection has ranged from 6 to 69% in several large series.^{80–84} In a recent IRAD review of 476 patients with type B dissection, 82 (17%) underwent open repair of the descending thoracic aorta, with a contemporary in-hospital mortality of 29.3%.⁸³ Given the variable results with open repair, it seems logical that thoracic endovascular aortic repair (TEVAR) will be preferred over open repair even in circumstances where the indication includes actual or threatened aortic rupture.

Although presently rarely indicated, central aortic graft replacement for type B aortic dissection presents significant technical challenges. To ensure anastomotic integrity, strips of polytetrafluoroethylene felt can be placed inside the true lumen and outside the aortic wall and sewn together with the aortic wall “sandwiched” in between.⁸⁵ In contradistinction, the introduction of glue aortoplasty is an important contribution to modern-day aortic dissection surgery. With the aorta transected and a sponge inserted in the true lumen to protect its diameter, the glue is applied for a length of 2 cm between the dissected layers, at a thickness of 2 mm. After 2 minutes, the aortic layers are fused and strengthened to accept a collagen-impregnated woven polyethylene terephthalate graft with a running polypropylene suture. The complexity of repair of the friable proximal aorta will lead to a prolonged cross-clamping time such that distal aortic perfusion with partial left heart bypass should be used to maintain visceral and spinal cord blood flow.

Figure 4 (a) Cartoon depiction of type A dissection limited to the ascending aorta. (b) Repair of type A dissection with replacement of the ascending aorta. Anatomic goals of replacement include (1) resection of aortic tear, (2) resuspension/repair or replacement of the aortic valve as necessary, (3) routine use of circulatory arrest to perform at least the distal anastomosis, and (4) reconstruction of the aortic layers so as to redirect flow into the true lumen and eliminate false lumen flow (this is successful only 50% of time).

ENDOVASCULAR TREATMENT OF AORTIC DISSECTION

Although medical therapy remains the current standard of care for uncomplicated type B aortic dissections, stent graft coverage of the aortic entry tear may ultimately prove to be the best solution to correct malperfusion syndromes in the acute phase and reduce late aortic-related complications by minimizing aneurysmal degeneration of the false lumen. When indicated, the goals of TEVAR for acute type B dissection include coverage of the proximal entry tear, expansion of the true lumen with restoration of flow to the visceral vessels, and obliteration of false lumen flow with subsequent complete thrombosis [see Figure 5]. When these components of therapy are successfully achieved, aortic remodeling should occur with subsequent prevention of future aneurysmal degeneration of the outer wall of the false lumen.

There are particular technical points of stent graft repair of aortic dissection that deserve emphasis. First, the placement

of uncovered stents over the entry tear within the proximal true aortic lumen is ill advised as this may lead to a retrograde dissection into the arch or ascending aorta.⁸⁶⁻⁸⁸ If a patient is to be considered a candidate for stent graft treatment, the location of the entry tear and proper recognition of the proximal zone of fixation are fundamental to procedural success, and the operator should have definitive knowledge of the three-dimensional aortic topography displayed on the preintervention CT scan prior to embarking on endovascular therapy. Endovascular repair of acute aortic dissection should be performed in an operating room with adequate fluoroscopic imaging. True lumen access should be obtained from either a brachial or femoral approach; typically, since the tear in type B dissection is distal to the left subclavian artery, rapid true lumen access is easily obtained through a right brachial approach. The proper true lumen position should then be confirmed

Figure 5 (a) Cartoon depiction of type B dissection with undeployed stent graft advanced to the level of the left carotid artery to ensure appropriate coverage of the entry tear. (b) Stent graft deployment to cover the proximal entry tear in the hope of inducing false lumen thrombosis and true lumen reexpansion. The latter should also alleviate “downstream” branch compromise caused by dynamic obstruction mechanisms. False lumen thrombosis in the thoracic aorta should, in theory, minimize subsequent aneurysmal expansion of the outer wall of the false lumen.

using intravascular ultrasonography to avoid inadvertent deployment of the stent in the false lumen [see Figure 6].

The Eurostar/United Kingdom registry report is the largest compendium of patients treated with thoracic aortic stent grafts to date.⁸⁹ In the combined registry, 131 patients with aortic dissection (5% proximal, 81% distal, 14% not classified) were treated with stent grafts; 57% had symptoms of rupture, aortic expansion, or side branch occlusion. Although no meaningful long-term data are available, primary technical success was achieved in 89% and 30-day mortality was 8.4%. Paraplegia occurred in 0.8% of those treated, and survival at 1 year after treatment was reported in 90% of 67 patients who had such follow-up.

A recent meta-analysis of stent graft repair for aortic dissection prior to 2005 identified 609 patients with a procedural success of 98.2%.⁹⁰ The 30-day mortality was 5.3% and was threefold higher in patients with acute dissection. The neurologic complication rate was 2.9%. A more recent review of the Nationwide Inpatient Sample (from 2005 to 2007) identified 5,000 patients who underwent repair of type B aortic dissections (3,619 open versus 1,381 TEVAR) and found that the TEVAR group had a significantly lower 30-day mortality (10.6% versus 19% for open repair).⁹¹

The Investigation of Stent-grafts in Aortic Dissection (INSTEAD) trial was a prospective, randomized, multicenter trial of stent grafting versus medical therapy for the treatment

Figure 6 (a) Intravascular ultrasonography (IVUS) of acute type B dissection with “floating” true lumen (TL) that is enhanced by the circle. Endovascular repair of acute type B aortic dissection. (b) IVUS of expanded TL after endovascular repair of acute type B dissection. (c) Thoracic aortography showing the stent graft in the descending thoracic aorta. The proximal portion of the graft (*black arrow*) is placed at the level of the left common carotid artery, covering the left subclavian artery to obtain proximal seal in normal aorta. (d) Thoracic aortography showing stent graft deployed with obliteration of the proximal false lumen. FL = false lumen.

of chronic, uncomplicated type B aortic dissection that found no difference in mortality between the two treatment arms. However, the stent graft group achieved false lumen thrombosis in over 90% of patients at 1 year (significantly higher than the medically treated group). This is significant because false lumen thrombosis and true lumen expansion (so-called aortic remodeling) may be considered a surrogate for prevention of late aneurysm formation. In addition, a recent study of 33 patients with acute type B dissections treated

with TEVAR showed aortic remodeling at 1 year with a decrease in total aortic volume, an increase in true lumen diameter, and a decrease in false lumen diameter, with thrombosis occurring in 90% of patients.⁹²

These preliminary data suggest that stent graft repair may ultimately become the treatment of choice for the majority of patients with distal dissections; the available data consisting largely of registry and/or single-center retrospective reviews permit only the conclusion that stent graft repair

of the aortic entry tear can afford effective treatment of complicated type B dissections, with the inherent advantages of a minimally invasive approach. The use of stent graft repair in the treatment of acute dissections holds promise to reduce both early complications and the progression over time to aneurysmal degeneration. The instantaneous and dramatic occurrence of false lumen thrombosis by coverage of the aortic entry tear appears to be a key determinant in the process; the significance of small distal fenestrations remains unknown. Furthermore, early treatment in the window of acute type B dissection appears to be associated with improved technical outcomes, consistent with the hypothesis that true lumen or septum malleability may diminish in the chronic phase of the disease. However, the available data are insufficient to apply TEVAR to all acute type B dissections, and medical therapy remains first-line therapy in uncomplicated patients. Clearly, comparative clinical trials are needed to clarify the role of stent graft repair in acute distal dissections.

OTHER ENDOVASCULAR APPROACHES

Mossop and colleagues from Australia described their experience in 25 patients with a staged thoracoabdominal and branch vessel endoluminal repair.⁹³ Initial treatment involved endograft closure of the proximal entry tear and bare metal, self-expanding Z-stenting of the true lumen, thereby supporting the true lumen and stabilizing the dissection flap. At the 1-week follow-up, secondary reentry tears were then sealed by a variety of endovascular approaches, including placement of branch vessel covered stents, short segment covered aortic endografts, and coil embolization of the false lumen [see Figure 7]. In their series over 4 years, they reported no Z stent migration or stent-related intimal trauma resulting in rupture. Induction of false lumen thrombosis was achieved in 85%. Survival at a mean follow-up of 2.5 years was 100%.

PERCUTANEOUS FENESTRATION

Fenestration of the intimal flap may be performed by several techniques using the combination of ultrasonography and fluoroscopy. Most commonly, fenestration is performed from the smaller (usually the true lumen) to the larger false lumen. Using a Roesch-Uchida, Brockenborough, or Colopinto needle or the back end of a 0.014 wire, a fenestration is created close to the compromised aortic branch. After the needle and a stiff wire are advanced from the true to the false lumen, a 5 French catheter is advanced into the alternate lumen. Confirmation of the position across the membrane is performed by contrast injection. Subsequently, an angioplasty balloon of at least 12 to 15 mm in diameter and 20 to 40 mm in length is used to create a fenestration tear [see Figure 8].

An alternative technique of fenestration has been termed the “scissors technique.”⁹⁴ Stiff guide wires are placed in each lumen from a single femoral access. A single long sheath is advanced over the two wires, thus dividing the membrane over this distance. Those familiar with use of the scissors technique have reported both clean longitudinal tears (the ideal result) and circumferential separation of the flap from the aortic wall with aorto-aortic intussusception (not ideal).⁹⁵

Lastly, the use of a snare to deliver a wire from one femoral access through the flap and down the contralateral femoral access has been described. By pulling this “U” down the distal aorta, a fenestration defect may be created with the same potential risk of intimal dehiscence described above. In light of these dramatic and unpredictable alterations in intimal flap anatomy and flow dynamics incurred by overly aggressive fenestration in the visceral aorta, the investigators with the largest series of patients currently recommend that percutaneous fenestration be limited to the distal aorta.⁹⁶ The ideal hemodynamic result for fenestration of the dissected intima is realized when there is equalization of peak systolic pressures between the two lumina in the aorta and the false lumen is decompressed.^{36,97,98}

In a series of 40 patients with malperfusion syndromes, 14 patients underwent combined stenting and balloon fenestration, 24 underwent stenting alone, and two underwent fenestration alone.⁹⁶ The location of the balloon fenestration was in the thoracic aorta in eight patients, in the upper abdominal aorta in three patients, and just above the aortic bifurcation in seven patients. Flow was restored to the ischemic territories in 37 of 40 patients (93%), but the 30-day survival was 75%. In follow-up past the 30-day perioperative period, five additional patients expired, with one of these deaths related to false lumen rupture and two of unknown etiology. This 30-day death rate of 25% compares favorably with the historical surgical series wherein operative mortality was reported to be up to 50%.⁹⁹ However, contemporary surgical series have demonstrated substantially improved operative mortality, even for those patients with mesenteric compromise⁸; thus, it is worth emphasizing that mortality in such patients is more often referable to delayed diagnosis than the morbidity of the intervention itself.

The effect of fenestration on the long-term outcome of false lumen expansion in patients with distal dissections is unknown as the false lumen remains pressurized and therefore at risk for continued progression to aneurysm. Beregi and colleagues reported a series of 46 patients treated by either stent graft therapy ($n=12$) or balloon fenestration ($n=34$) for peripheral ischemic complications of acute aortic dissection and found that a decrease in aortic diameter occurred in patients treated with stent grafts, whereas the aortic diameter in those with balloon fenestration grew.¹⁰⁰ Indeed, it is likely that as further experience with TEVAR of the proximal entry tear is gained, fenestration and stenting of branch vessels will be used as an adjunct to stent grafting rather than definitive therapy.

OPEN SURGICAL REPAIR

Since dynamic obstruction at the aortic level is the most common mechanism of malperfusion syndromes, surgical fenestration has been the most commonly applied procedure.⁶ Because the threat of proximal aortic rupture is rare, many surgeons have favored a complication-specific approach in which the intervention is directed toward restoring flow to acutely affected organs.^{8,101} The fundamental technique of surgical fenestration is wide resection of the dissected septum to relieve aortic obstruction by equalizing flow between the true and false lumina [see Figure 9]. It may be desirable to extend the septectomy into the visceral segment,

Figure 7 Cartoon depiction of the use of a combination of covered and bare metal stents to completely obliterate the false lumen in acute type B dissection. (a) Stanford type B dissection with entry tear distal to the left subclavian artery and fenestrations at branch artery ostia. (b) Covered stent graft used to seal the proximal entry tear (with coverage of the left subclavian artery to obtain adequate seal). Bare metal stents then obliterate the thoracic false lumen to the level of the renal arteries. False lumen flow remains in the abdominal portion of the dissection as a result of multiple entry points. (c) Interval placement of covered stents over false lumen entry points with complete obliteration of the false lumen.

permitting direct inspection or repair of the ostia of the mesenteric and renal vessels.¹⁰² Experience has demonstrated that the duration of supraceliac clamping can be limited to the 20-minute range, with repositioning of the clamp to an infrarenal location following closure of the visceral segment aortotomy. Interposition of a short segment polyester graft in the infrarenal aorta facilitates reconstruction of the aortic

layers at the distal anastomosis with the double-layer polytetrafluoroethylene felt technique. Our posture relative to extending the fenestration or septectomy into the visceral aortic segment is dictated by the anatomic complexity displayed on the CT scan. Small aortic diameter, total absence of visceral artery flow, the dissected septum extending directly to or beyond a vital branch orifice, and radiographic

Figure 8 Cartoon depiction of endovascular fenestration. (a) The left renal artery (coming off the false lumen) made to originate from the true lumen. This requires stenting using either a covered or bare metal stent. (b) A balloon is then used to enlarge natural fenestrations in the dissection flap, and a stent can be used to keep this fenestration open.

evidence of intussuscepted septum into a renal/mesenteric vessel are all considerations that prompt extension of the aortotomy into the visceral segment. Such an approach also permits direct repair of a static obstruction, that is, where the branch vessel itself is dissected. This can be accomplished by circumferential suture of the vessel intima to the aortic wall at the ostia. Since continuous exposure of the visceral segment is desirable in surgical treatment of malperfusion syndrome, we prefer left flank approaches for this procedure. Depending on body habitus, a ninth or 10th interspace thoracoabdominal approach is used to allow for complete infradiaphragmatic aortic exposure and transperitoneal inspection of the viscera and palpation of the superior mesenteric artery pulse caudal to the mesocolon. At a median

follow-up of 19 months, no significant aortic dilatation occurred with such aortic tailoring as a surgical technique.¹⁰²

Advocates of surgical fenestration for malperfusion syndromes have asserted that the “surgical” morbidity and mortality rates quoted to support endovascular therapies are outdated and strongly influenced by delays in diagnosis and treatment.¹⁰³ Elefteriades and colleagues reported a survival of 65% at 1 year, 57% at 3 years, 50% at 5 years, and 28% at 10 years for patients treated with a “complication-specific” approach.¹⁰⁴ Overall, of the 14 patients in the total experience treated by open fenestration, their actuarial survival was 77%, 77%, and 53% at 1, 3, and 5 years, respectively. None of the surgically fenestrated patients were noted to have expansion of their aortic diameters on follow-up.

Figure 9 Technique of surgical abdominal aortic fenestration. (a) Dissection involving the visceral segment of the aorta. (b) If static obstruction of the renal or visceral vessels is suspected based on axial imaging studies, the fenestration can be carried onto the visceral aortic segment. The left kidney has been swept anteriorly; note that the left renal artery is perfused from the false lumen. The septum is incised to expose the origins of the celiac/superior mesenteric/right renal artery perfused via the true lumen. (c) Direct suture repair of the vessel ostium may be required, herein shown at the left renal origin, whose orifice abuts the circumferential terminus of the dissection. (d) After septectomy in the visceral segment, the outer aortic wall is closed over Teflon felt and the clamp is moved to the infrarenal aorta, which is most conveniently reconstructed with a tube graft.

A recent report from the Mayo Clinic affords perspective on both the infrequent need for and the durability of surgical fenestration.¹⁰⁵ From their database of 857 patients with a diagnosis of aortic dissection, only 321 patients underwent surgical intervention of any kind and only 14 patients underwent surgical fenestration during the study period—1.6% of the total study population. Surgical fenestration relieved the malperfusion syndrome for all patients with organ or limb ischemia. Operative mortality was 43% (3 of 7) in the acute dissection group; seven patients were treated in the chronic phase of the disease, with no mortality. Follow-up at a mean of 5.1 years for the 11 survivors revealed no evidence of aneurysm formation at the site of fenestration. The authors noted that in comparison of surgical fenestration with series of endovascular fenestration, the likelihood of subsequent aortic complications related to expansion or rupture of the false lumen may be greater in those patients treated by endovascular means. Therefore, although endovascular fenestration may offer more rapid restoration of perfusion, its durability would seem less than surgical fenestration techniques (see below).¹⁰⁵

Our cumulative experience affords a perspective over a 35-year period involving some 200 patients with acute aortic dissection treated during the 1990s and in part clarifies the role of open surgical fenestration and peripheral endovascular intervention in patients with malperfusion

syndromes.⁸ Nearly a third of the patients had evidence of branch occlusion; 17 (32%) of these 53 patients underwent peripheral vascular intervention to restore circulation. The overall mortality rate in the interval 1990 to 1999 was significantly lower when compared with an earlier report from 1965 to 1986 (18% versus 37%, $p < .006$).⁸ In discerning the factors associated with improved results over time, three variables were important: (1) aortic rupture occurred in just 6% of patients versus 18% in the previous interval; presumably, patients were being diagnosed and referred more promptly; (2) the impact of branch occlusion on mortality was no longer significant, implying that recognition and treatment of malperfusion syndromes had improved overall results; and (3) mortality in patients with mesenteric ischemia had improved to 37%, whereas an 87% mortality rate was observed in our earlier report. Recently, the IRAD data implicated mesenteric ischemia as responsible for 15% of all deaths related to acute dissection.⁵ For patients with mesenteric or renal malperfusion syndromes, surgical fenestration was used in nine patients. Restoration of flow was successful in all patients, and all patients so treated survived, whereas two deaths occurred in patients with mesenteric ischemia managed with percutaneous fenestration.

Open aortic fenestration is an excellent method of restoring circulation to vascular territories affected by malperfusion syndromes, especially when mesenteric and renal beds

are involved, and affords the opportunity to assess bowel viability and plan second-look procedures. Treatment priority should be assigned to the most life-threatening condition in patients with acute aortic dissection. The presence of mesenteric ischemia assumes such priority in virtually all patients, and constitutes an exception to prompt central aortic repair in those with type A dissections.

Natural History

The primary late complication of aortic dissection is aneurysmal dilatation of the outer wall of the false lumen; of patients surviving acute dissection, 25 to 40% will progress to have aneurysmal dilation of the dissected aorta despite medical therapy.^{106,107} In most clinical series of thoracoabdominal aneurysms, some 20% of cases are the sequelae of chronic dissection, for which conventional open repair is typically the only treatment option in contemporary practice.¹⁰⁸ Indeed, a variety of technical and anatomic considerations indicate that stent graft repair of aneurysms of chronic dissection etiology remains a major challenge.¹⁰⁹ Factors that appear to have a significant impact on chronic aneurysm development after dissection include poorly controlled hypertension, maximal aortic diameter of at least 4 cm in the acute phase, and continued patency of the false lumen.¹¹⁰ Furthermore, some 10 to 20% of those with dissection will subsequently experience late rupture of the aneurysm,¹¹⁰ and conventional surgical repair of such lesions is considerably more complex than with degenerative aneurysms.

LONG-TERM SURVIVAL

A recent review of the IRAD data focused on long-term survival of patients with acute aortic dissection. In an examination of 242 consecutive patients discharged alive after type B dissections, Tsai and colleagues found that the 3-year survival for patients treated medically was 77.6%; for those treated surgically, it was 82.8% and 76.2% for those treated with stent graft repair.¹¹¹ Independent predictors of long-term mortality included female gender, a history of previous aortic aneurysm, atherosclerosis, renal failure, and in-hospital hypotension or shock.¹¹¹ An examination of the 273 type A dissection patients discharged alive found that survival for patients treated with surgery was 90.5% at 3 years versus 68.7% for those treated medically.¹⁵ Independent predictors of mortality in this cohort included atherosclerosis and previous cardiac surgery.¹⁵ These studies show that although posthospital survival is excellent after type A dissection, nearly one quarter of those with type B dissections died within 3 years, suggesting that current treatment strategies are inadequate.

LATE THERAPY

Aneurysms that are the sequelae of chronic dissection tend to be more extensive and occur in younger patients compared with degenerative aneurysms. Treatment with effective beta blockade is an essential feature of long-term therapy and follow-up. The rationale of such therapy is based on the recognition that patients with aortic dissection have a systemic illness that places their entire aorta at risk for further dissection, aneurysm, or rupture. Guidelines

recommend progressive upward titration of beta blockade to achieve a blood pressure less than 125/80 mm Hg in usual patients and less than 120 mm Hg in those with Marfan syndrome. In addition, aggressive beta blockade has been shown to retard the growth of the aortic root in Marfan syndrome patients and may have a similar effect on the thoracoabdominal aorta.¹¹² Serial imaging is the cornerstone of long-term follow-up, and axial imaging modalities should encompass the entire aorta. Although in the developmental stages at present, branched stent graft technologies will likely have an important role in the future management of patients with aneurysms of chronic dissection etiology.¹¹³

Intramural Hematoma and Penetrating Aortic Ulcer

Two aortic entities related to aortic dissection deserve mention. An intramural hematoma (IMH) represents a collection of blood that is confined to the aortic media, whereas a penetrating aortic ulcer (PAU) is a defect in the elastic lamina of the aortic wall that leads to localized medial disruption and potential rupture. These are two closely related (possibly the same) aortic conditions that commonly cause diagnostic confusion with classic aortic dissection [see Figure 10]. Such confusion is related to the fact that these entities share the feature of an intimal violation with the flowing blood gaining entry and/or propagating between the aortic wall layers (usually within the media), and IMH and PAU may present concurrently. PAU is often noted as a radiographic curiosity on CT scans obtained for evaluation of the thoracic aorta, whereas IMH is a dissection process wherein the defining features include absence of an “intimal flap” and (as implied by the name) a thrombosed false lumen.

ETIOLOGY AND DIAGNOSIS

In both conditions, symptomatic patients present with the abrupt onset of severe pain in the chest, neck, back, and/or abdomen that is typical of acute aortic syndrome. Paradoxically (and unlike classic aortic dissection), both are manifestations of degenerative aortic pathology, typically occurring in older patients with significant hypertension and often with diffuse degenerative atherosclerotic disease of the thoracic aorta. IMH of the thoracic aorta has been characterized as a distinct clinical entity whose distinguishing radiographic features are the absence of direct communication between the thrombus in the false lumen and the true lumen and the absence of a definable intimal flap (as seen with classic aortic dissection) or penetrating ulcer.^{114,115} IMH extent is variable in terms of the length of the aorta involved, circumference, and direction of propagation. The etiology of IMH was initially thought to involve spontaneous rupture of the vasa vasorum within the medial layers of the aortic wall, which will occasionally evolve into a PAU (a rare event). More consistent with our own observations, a PAU phenomenon is usually the origin of IMH, and whether the ulcerlike projection is radiographically demonstrated is mere serendipity.¹¹⁶ Indeed, in the Mayo Clinic series, approximately 80% of patients with PAU had an associated IMH.¹¹⁷ PAU is used to describe those lesions when a caplike projection of contrast is seen (on CT scan) beyond the usual luminal aortic boundary [see Figure 11]. In this instance, the atherosclerotic

Figure 10 (a) Cartoon depiction of intramural hematoma. (b) Cartoon depiction of penetrating aortic ulcer.

lesion penetrates the internal elastic lamina and facilitates hematoma formation within the media. Further propagation of this flap is thought to be prevented by the presence of atherosclerotic disease in the aorta (a rare finding in classic aortic dissection).¹¹⁸

TREATMENT

Although the natural history of asymptomatic type B IMH and PAU has been complete resolution in 50 to 80% of patients,¹¹⁸ progression to classic dissection or aneurysmal degeneration of the aorta can occur.^{116,119} The IRAD database

examined 1,010 patients who presented with symptoms of the acute aortic syndrome and identified a 5.7% incidence of IMH. This affected the descending aorta in 60% of cases, whereas classic aortic dissection more commonly affected the ascending aorta (65% of cases). The overall mortality of IMH was similar to that of classic aortic dissection, 20.7% versus 23.9%, both for proximal (39.1% versus 29.9%) and distal (8.3% versus 13.1%) locations. Among the 51 patients whose initial diagnostic study revealed IMH, eight (16%) progressed to aortic dissection on a second imaging study. A normal aortic diameter in the acute phase was the best predictor of IMH regression without complications. The IRAD investigators recommended prompt surgical therapy for IMH involvement of the ascending aorta. Intense medical therapy (goal of systolic blood pressure <120/80, heart rate <60 beats/min) with serial imaging was recommended for involvement of the arch and descending aorta.¹²⁰

A recent report of 35 patients with IMH detailed a significant correlation between disease progression and initial aortic diameter and/or hematoma thickness. Those patients with an initial aortic diameter greater than 40 mm had a 30-fold increased risk of progression to either aneurysm formation or rupture. In addition, hematoma thickness greater than 1 cm was associated with a ninefold increased risk of progression. This suggests that the degree of separation of the aortic wall layers may contribute to chronic aneurysmal degeneration.¹²¹

Although such focal pathology may be ideally suited for stent graft repair, patients with incidental asymptomatic IMH or PAU of the descending aorta are currently managed with medical therapy. Tittle and colleagues detailed their experience with 45 patients with symptomatic PAU and IMH.¹²² In this cohort, 33% had rupture on admission and 53% required operation. Patients with lesions involving the ascending aorta were more likely to undergo surgical repair (83%), whereas only 50% of patients with involvement of the descending thoracic aorta were operated on. Indications for intervention include aortic diameter greater than 6 cm,

Figure 11 Computed tomographic angiogram of penetrating aortic ulcer (red arrow) in the descending thoracic aorta.

rupture, impending rupture, or major progression in size despite medical therapy.¹¹⁶ Those patients with involvement of the ascending aorta are usually treated surgically because of the high risk of cardioaortic complications. Surveillance imaging of patients with IMH or PAU treated medically should be frequent, especially those with evidence of aneurysmal dilation.

Conclusion

Considerable progress has been demonstrated in the overall results of treatment of acute aortic dissection. A broad clinical awareness of aortic dissection and improved methods of diagnosis have helped reduce the morbidity and mortality associated with this disease process. Indeed, clinicians who understand the principles of both medical and surgical management of aortic dissection can effectively separate patients who require surgical intervention from those who can be managed medically with serial imaging studies. Although open surgery has been the standard of care for many years, it is clear that a wide variety of thoracic aortic pathologies are amenable to endovascular therapy. As stent graft technology continues to evolve, it is likely that it will become the primary method of treatment of acute aortic dissection in the future.

Financial Disclosures: None Reported

1 INITIAL MANAGEMENT OF LIFE-THREATENING TRAUMA

Frederick A. Moore, MD, FACS, and Ernest E. Moore, MD, FACS

Initial Approach to the Critically Injured Patient

Salvage of the critically injured patient is optimized by a coordinated team effort in an organized trauma system. Management of life-threatening trauma must be prioritized according to physiologic necessity for survival—that is, active efforts to support airway, breathing, and circulation (the ABCs) are usually initiated before specific diagnoses are made. In this chapter, we outline a systematic approach to severely injured patients within the so-called golden hour. The discussion is divided into prehospital care and emergency department (ED) management; the ED component is further divided into (1) primary survey with initial resuscitation, (2) evaluation and continued resuscitation, and (3) secondary survey with definitive diagnosis and triage.

Prehospital Care

INTERVENTION AT INJURY SITE

Resuscitation and evaluation of the trauma patient begin at the injury site. The goal is to get *the right patient to the right hospital at the right time* for definitive care. First responders (typically, firefighters and police) provide rapid basic trauma life support (BTLS) and are followed by paramedics and flight nurses with advanced trauma life support (ATLS) skills. Medical control is ensured by preestablished field protocols, radio communication with a physician at the base hospital, and subsequent trip audits. Management priorities of BTLS on the scene are to (1) assess and control the scene for the safety of the patient and the prehospital care providers, (2) tamponade external hemorrhage with direct pressure, (3) protect the spine after blunt trauma, (4) clear the airway of obstruction and provide supplemental inspired oxygen, (5) extricate the patient, and (6) stabilize long-bone fractures. Whereas the benefits of BTLS are undisputed, the merits of more advanced interventions remain controversial.¹ Airway access, once considered a major asset of the care provided by paramedics and flight nurses, has now been questioned, not only because missed tracheal intubation is a concern but also because unintentional hyperventilation (hypocarbica) is detrimental in the setting of traumatic brain injury (TBI) and during cardiopulmonary resuscitation (CPR).² Moreover, the value of intravenous (IV) fluid administration remains controversial.^{3,4}

FIELD TRIAGE

When it is geographically and logistically feasible, critically injured patients should be taken directly to a designated level I trauma center or to a level II trauma center if a level I trauma center is more than 30 minutes away. The currently available field trauma scores, however, are not reliable in making this triage decision. The development of field triage criteria has paralleled the development of trauma centers. The decision is based on a practice algorithm called a “decision scheme.” The first field triage decision scheme was published by the American College of Surgeons in 1986, with subsequent updates in 1990, 1993, 1999, and 2006.⁵ The decision scheme has four steps that the emergency medical service (EMS) provider proceeds through after measuring vital signs and level of consciousness to decide if the patient should be transported to a higher level trauma center [see Table 1]. Because the potential harm associated with undertriage is high and could result in death or substantial morbidity and disability, criteria were initially chosen to err on the side of minimizing undertriage rather than minimizing overtriage. However, overtriage results in an overuse of financial and human resources, overcrowding of trauma centers, and increased EMS transport times. Target levels for undertriage rates within a trauma system range from 0 to 5% of patients requiring level I or level II trauma center care, whereas levels of overtriage vary from 25 to 50%. As field triage continues to evolve on the basis of new research findings, overtriage rates might be reduced while maintaining low undertriage rates.

DECLARATION OF DEATH AT SCENE

The determination that care is futile during prehospital evaluation is best made on the basis of the cardiac rhythm. Asystole justifies declaration of death at the scene, and profound bradycardia (heart rate [HR] < 40 beats/min) has been shown to signal an unsalvageable situation.⁶

ED Management

ARRIVAL AT HOSPITAL UNDER ACTIVE CPR

When a patient arrives in the ED after prehospital CPR has been initiated,

Initial Approach to the Critically Injured Patient

Communicate with base hospital

Field triage: Level I, II, or III facility

Assemble trauma team:

- Trauma surgeon
- ED physician
- Surgical specialist
- Radiology technicians
- Nurses
- Respiratory technicians

Ensure ancillary services:

- OR
- CT scanning
- Blood bank
- Interventional radiology

ED = emergency department; CT = computed tomography; ECG = electrocardiogram; EMT = emergency medical technician; NG = nasogastric; SICU = surgical intensive care unit; BP = blood pressure; CVP = central venous pressure; DPL = diagnostic peritoneal lavage; OR = operating room

Urban: < 15 minutes (Rural: > 30 minutes)

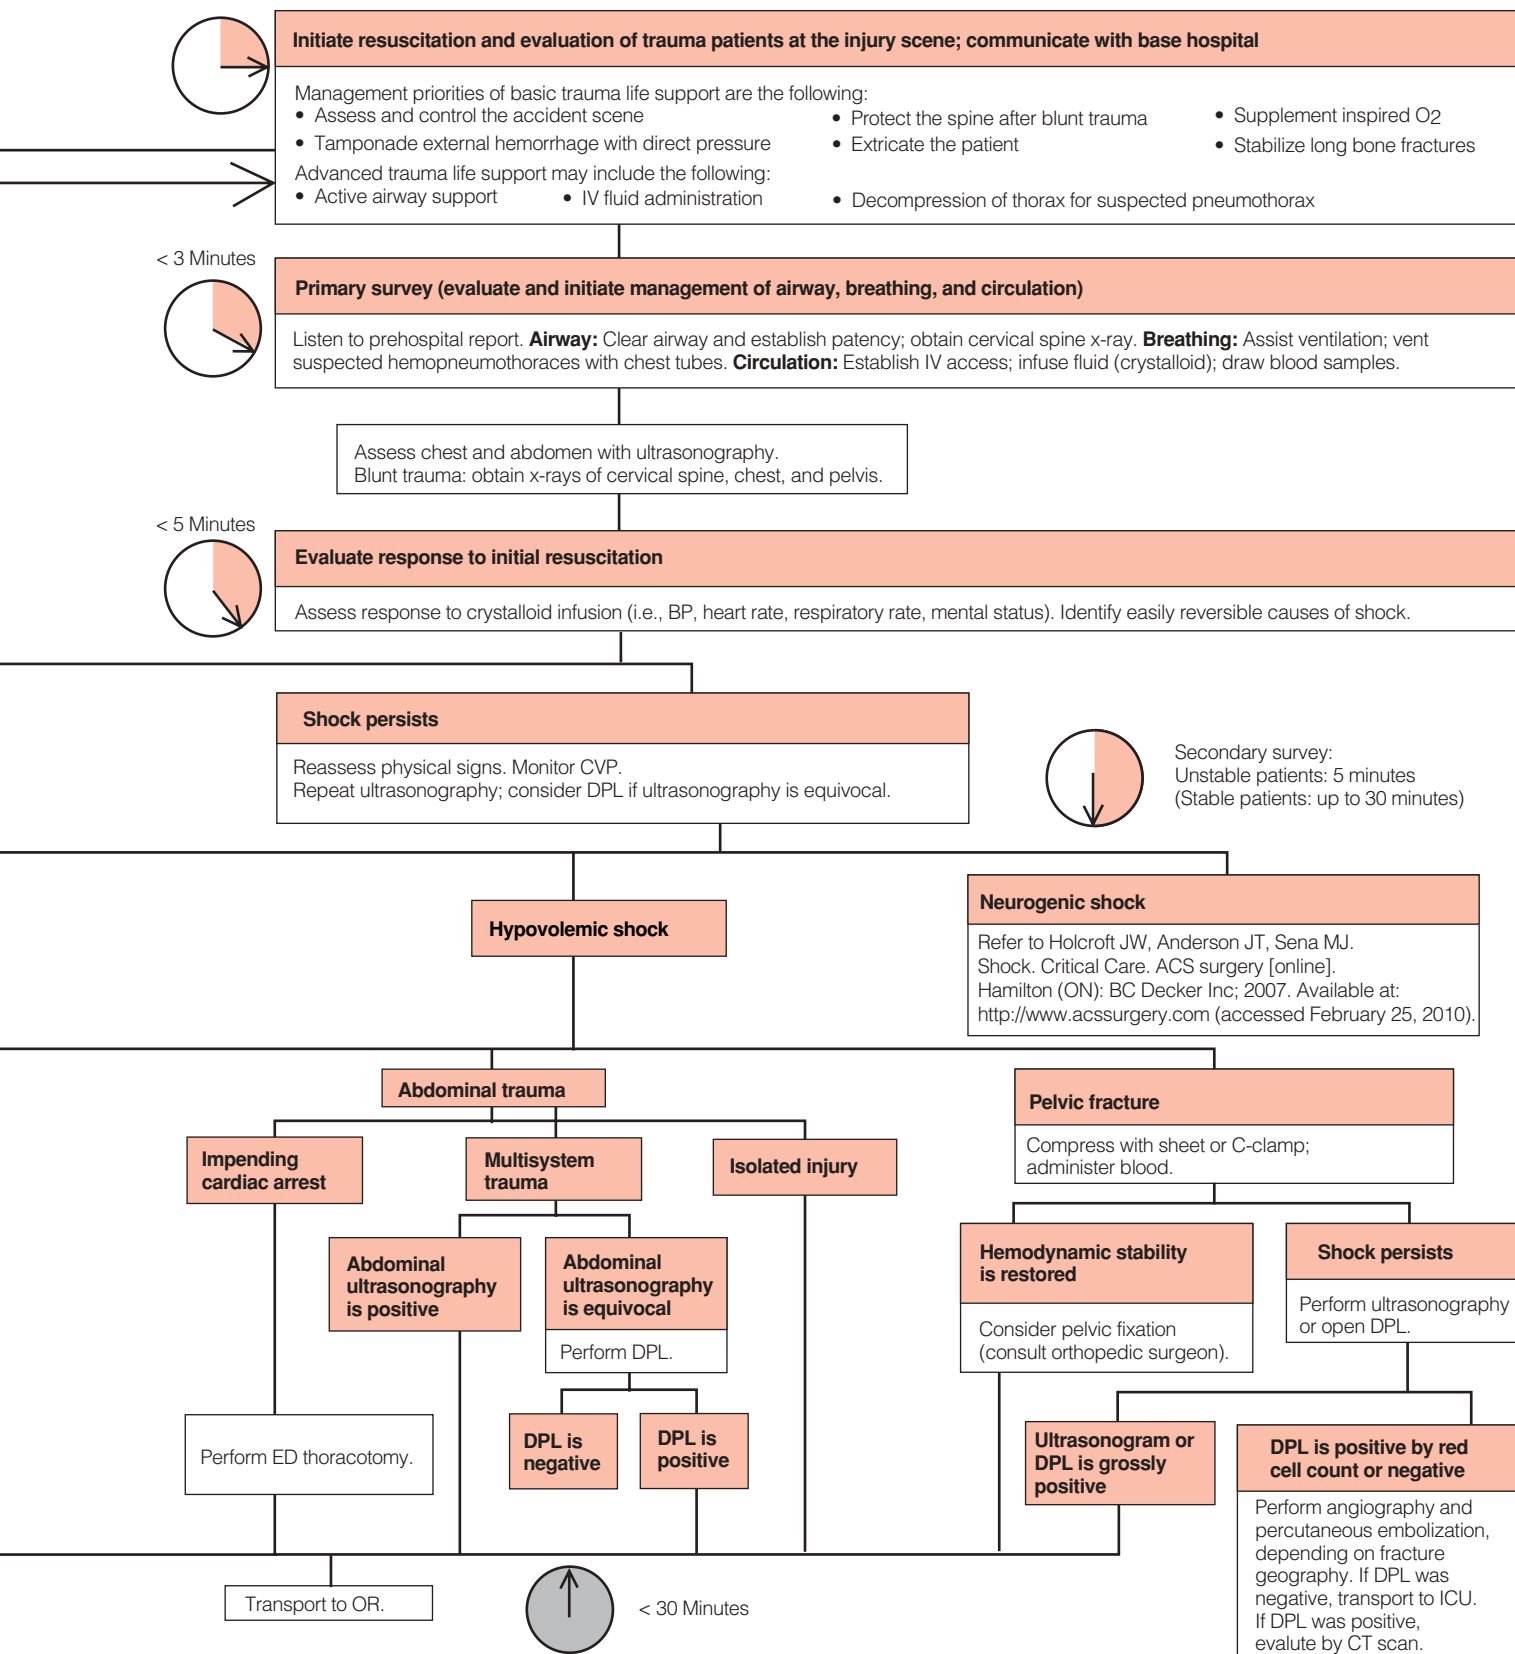

Table 1 2006 Field Triage Decision Scheme Recommendations

Step one: physiologic criteria - Glasgow Coma Scale of < 14 - Systolic blood pressure of < 90 mm Hg - Respiratory rate of < 10 or > 29 breaths per minute (< 20 in infant aged < 1 year) Step two: anatomic criteria - All penetrating injuries to head, neck, torso, and extremities proximal to elbow and knee - Flail chest - Two or more proximal long-bone fractures - Crushed, degloved, or mangled extremity - Amputation proximal to wrist and ankle - Pelvic fractures - Open or depressed skull fracture - Paralysis Step three: mechanism-of-injury criteria - Falls - Adults: fall > 20 feet (one storey = 10 feet) - Children aged < 15 years: fall > 10 feet or two to three times child's height - High-risk automobile crash - Intrusion: > 12 inches to the occupant site or > 18 inches to any site - Ejection (partial or complete) from automobile - Death in same passenger compartment - Vehicle telemetry data consistent with high risk of injury - Automobile versus pedestrian/bicyclist thrown, run over, or with significant (> 20 mph) impact - Motorcycle crash > 20 mph Step four: special considerations - Age - Adults aged > 55 years - Children aged < 15 years - Anticoagulation and bleeding disorders - Burns - Without other trauma mechanism: triage to burn facility - With trauma mechanism: triage to trauma center - Time-sensitive extremity injury - End-stage renal disease require dialysis - Pregnancy > 20 weeks - EMS provider judgment
--

EMS = emergency medical service.

Table 2 Guidelines for Declaring Patients Dead on Arrival to the Hospital

Penetrating trauma - Prehospital CPR for > 15 min with no signs of life - Asystole without pericardial tamponade Blunt trauma - Prehospital CPR for > 10 min with no signs of life - Asystole

CPR = cardiopulmonary resuscitation.

ultimate goal is to establish adequate oxygen delivery to the vital organs. This is accomplished by first progressing through the ABCs: airway control with cervical spine precautions, assisted breathing with ventilation, and empirical tube thoracostomy to relieve a pneumothorax if indicated. These maneuvers are carried out to maximize oxygen delivery to the alveoli. Support of the circulation (tamponade of external bleeding and fluid administration) is instituted to restore effective blood volume, thereby enhancing myocardial performance and thus oxygen delivery to the tissues.

Unstable patients fall into two categories: those who respond to initial intervention and those who do not. Early nonresponders are challenging because they require an immediate lifesaving intervention. The key is to perform the correct intervention before the patient dies. Patients who respond to initial interventions can be demanding because a subset of them have only a finite time window before shock recurs. Multiple diagnoses must be considered before definitive triage is possible. The clinician must rapidly formulate a differential diagnosis and then sequentially initiate the appropriate diagnostic tests.

Airway and Breathing

After blunt trauma, airway control should proceed on the assumption that an unstable cervical spine fracture exists; thus, hyperextension of the neck must be avoided. Airway management in the seriously injured victim can usually be accomplished with simple techniques, but it is occasionally stressful. Evaluation begins by asking the patient a question such as "How are you?" A response given in a normal voice indicates that the airway is not in immediate jeopardy; a breathless, hoarse response or no response at all indicates that the airway may be compromised.

Airway obstruction and hypoventilation are the most likely causes of respiratory failure. The critical decision is whether active airway intervention is needed. The first maneuver is to clear the airway of debris and to suction secretions. In the obtunded patient, this procedure is followed by elevation of the angle of the mandible to alleviate pharyngeal obstruction and placement of an oropharyngeal or nasopharyngeal tube to maintain airway patency. Supplemental oxygen is given via a nasal cannula (6 L/min) or a nonrebreathing oxygen mask (12 L/min). Airway patency, however, does not ensure adequate ventilation, nor does a normal arterial oxygen saturation (Sao₂) on pulse oximetry. Clinical evidence of hypoventilation includes poor air exchange at the nose and mouth, diminished breath sounds, and decreased chest wall excursion; the most likely causes are head injury, spinal cord transection, hemopneumothorax, flail chest, and profound

the critical question is whether to perform a resuscitative thoracotomy. The prognosis for blunt trauma patients is poor because the major causes of cardiopulmonary arrest after blunt trauma (e.g., massive brain injury, high spinal cord injury, and exsanguination from multiple injuries) are difficult to reverse. In contrast, patients with stab wounds to the heart are frequently salvageable if cardiac arrest occurs because of cardiac tamponade. In most cases, the heart can be resuscitated by simply decompressing the pericardium, given that blood volume is usually maintained. Guidelines for terminating resuscitation are based on the mechanism of injury, the duration of CPR, the presence of signs of life (e.g., pupillary response, respiratory effort, or motor activity), and the presence of asystole documented by cardiac monitoring [see Table 2].⁷

PRIMARY SURVEY AND INITIAL RESUSCITATION

During initial assessment, an empirical sequence of lifesaving therapeutic and diagnostic procedures is pursued. The

shock. Suspected hemopneumothoraces should be vented immediately with large-bore chest tubes inserted via the midlateral thorax.

Cervical spine protection is integral to airway management but should not be allowed to delay necessary intervention. The majority of significant spinal injuries in adults arriving alive at the ED are at the C5 to C7 levels. In children 8 years old or younger, the most frequent site of spinal injury is between the occiput and the C3 level. Significant spinal cord injury without radiographic abnormalities (i.e., the SCIWORA syndrome) is a relatively rare event (0.5% of patients undergoing radiography), and the data on its relative frequency in children and in adults are conflicting.⁸ A fractured cervical spine is usually tender to direct palpation in alert patients, but pain may be masked by distracting injuries.⁹ Even good-quality cross-table lateral cervical spine films may not detect 15% of unstable fractures. Accordingly, in patients who cannot have C-spine injury ruled out by clinical criteria, a cervical collar is left in place until the cervical spine has been evaluated for bony and ligamentous integrity by computed tomographic (CT) scanning.¹⁰

Bag-mask ventilation is an effective temporizing measure, but it consumes the attention of a skilled trauma team member, it may insufflate air into the stomach, and it can be resisted by spontaneously breathing patients. It is also ineffective in the presence of severe maxillofacial trauma. The decision for urgent airway control is made on clinical grounds; there often is no time to obtain a confirmatory arterial blood gas (ABG) analysis. Persistent airway obstruction or signs of inadequate ventilation mandate prompt intervention. Patients with expanding neck hematomas, deteriorating vital signs, or severe head trauma are also best managed with an aggressive airway approach.

The method of airway control depends on (1) the presence of maxillofacial trauma, (2) overall patient condition, and (3) the experience of the physician. Patients in respiratory distress with severe maxillofacial trauma warrant operative intervention. Cricothyrotomy is the preferred approach in adults and has replaced tracheostomy in the ED [see *Figure 1*]; the rare exceptions are in patients with major laryngeal trauma or extensive tracheal disruption. Percutaneous transtracheal ventilation may be safer than both of these surgical procedures for temporary airway management, particularly in children. In all other patients, the current standard approach is rapid sequence intubation (RSI) of the trachea orally with inline immobilization [see *Table 3*].⁹ In adults, a large (8 mm internal diameter) cuffed endotracheal tube is inserted to a distance of 23 cm from the incisors. In children, tube size is gauged to equal the diameter of the little finger. The proper depth (in centimeters) to which the tube should be inserted can be estimated by multiplying the tube's internal diameter (in millimeters) by 3. A chest x-ray should be obtained as soon as possible to rule out the possibility of right mainstem intubation.

Intubated patients should be placed on a high fraction of inspired oxygen ($F_{I}O_2$), and their SaO_2 should be monitored by pulse oximetry. Generally, a low SaO_2 is easily treated by increasing the $F_{I}O_2$. Patients who do not respond when the $F_{I}O_2$ is increased to 100% should be treated with low levels of positive end-expiratory pressure (PEEP) once adequate volume status is ensured. Positive-pressure ventilation

impedes return of blood to the heart; as a result, emergency intubation of a hypovolemic patient can adversely affect cardiac output. Hyperventilation should also be avoided. This can cause auto-PEEP, which can adversely affect cardiac output. Additionally, a low arterial carbon dioxide tension ($Paco_2$) can cause cerebral vasoconstriction, which can be deleterious in patients with TBI. An ABG analysis should be obtained to assess pH, $Paco_2$, and base deficit. The use of end-tidal capnography ($EtCO_2$) has been recommended as a surrogate measure of ventilation. However, trauma patients frequently suffer from impaired pulmonary ventilation/perfusion, and a recent study showed that $EtCO_2$ had low correlation with $Paco_2$. Therefore, $EtCO_2$ should not be used to guide ventilation in intubated trauma patients in the ED.¹¹

Circulation

Once alveolar ventilation is ensured, the next priority is to optimize oxygen delivery by maximizing cardiovascular performance. External hemorrhage is controlled by means of manual compression, and empirical volume loading for presumed hypovolemia via large-bore IV cannulas is initiated. The size, number, and sites of IV catheters depend on the degree of shock present and on estimates of injury severity. If the patient arrives in shock or has obvious multiple injuries, a short 14 French catheter should be placed in each antecubital vein. When vascular collapse precludes peripheral percutaneous access in an adult, the alternative is cannulation of the femoral or the subclavian vein by means of the Seldinger technique. We have found the supraclavicular subclavian approach to be useful in the ED.¹² Venous access should be avoided in regions with potential penetrating vascular injuries (e.g., lower neck, upper chest, pelvis, or groin).

Intraosseous infusion through a cannula placed in the medullary cavity of a long bone is a safe and efficacious method for emergency vascular access in infants and children younger than 6 years. This procedure is typically performed in the anteromedial aspect of the tibial plateau in an uninjured extremity; the distal femur, the distal tibia, and the sternum are other potential sites. Intraosseous infusion generally allows administration of sufficient fluid to facilitate subsequent cannulation of the venous circulation.¹³ If access remains problematic in children, great saphenous vein cut-down at the groin is the preferred route because inadvertent femoral artery injury with the percutaneous approach may result in limb-threatening vasospasm. With establishment of the first IV line, blood should be drawn for hematocrit, white blood cell (WBC) count, electrolyte concentrations, blood-group typing, coagulation profile, and toxicology screen as indicated.

Isotonic crystalloid is used for initial resuscitation in the ED.¹⁴ Lactated Ringer (LR) solution is preferred to normal saline (NS) unless the patient has an obvious brain injury. Excessive early administration of crystalloids has been identified as a risk factor for adverse outcomes; accordingly, the amount infused should be monitored closely.¹⁵ If the patient does not respond to crystalloid infusion at levels exceeding 30 mL/kg, blood should be administered. LR solution and banked blood should not be infused through the same IV line.

Figure 1 The technique for cricothyrotomy is illustrated here. The larynx is stabilized with one hand, and a 2 cm vertical incision is made over the cricothyroid space. The cricothyroid membrane is palpated and incised horizontally. A Trousseau dilator is inserted and spread vertically for visualization of the subglottic space (left). A tracheal hook is used to retract the inferior border of the thyroid cartilage as a tracheostomy tube with a 6 mm internal diameter is inserted into the trachea (right).

Early empirical blood transfusions are indicated in patients who arrive in severe shock or who have injuries associated with significant bleeding (e.g., a vertical shear pelvic fracture or bilateral femur fractures), especially if the patients are elderly. Type-specific blood should be available within 20 minutes. If type-specific blood is not available, reconstituted O-negative packed red blood cells (PRBCs) may be used. Type O-negative PRBCs have no cellular antigens; therefore, the risk of major hemolytic reactions caused by patient antibodies attacking donor RBC antigens is minimal. When O-negative PRBCs are unavailable, O-positive PRBCs

may be used. The patient will become sensitized to the Rh factor, which is significant for women of childbearing age. Protocols for massive transfusions (defined as > 10 units PRBCs in 6 hours) should be established with the blood bank to ensure prompt availability of blood products for patients arriving with life-threatening bleeding.¹⁶ Recent studies demonstrate that patients arriving with severe bleeding are coagulopathic and benefit from early administration of fresh frozen plasma (FFP).

Also germane to the initial period of massive blood transfusion are the potential complications of acidosis, hypothermia, and hypocalcemia. Moderate hypothermia (< 32°C) causes platelet sequestration and inhibits the release of platelet factors that are important in the intrinsic clotting pathway. In addition, hypothermia has consistently been associated with poor outcome in trauma patients. Core temperature often falls insidiously because of exposure at the scene and in the ED and because of administration of resuscitation fluids stored at ambient temperature. The first step is to prevent further heat loss by covering the body (including the head) and infusing warm blood and fluid. Another simple technique is to heat and aerosolize ventilator gases. Active external rewarming with heating blankets and increased room temperature should also be employed. These techniques are not, however, very effective in reversing established hypothermia.

The use of bicarbonate in the treatment of systemic acidosis remains controversial. Moderate acidosis (pH < 7.20) impairs coagulation, myocardial contractility, and oxidative metabolism. Acidosis in the trauma patient is caused

Table 3 10 Steps in Rapid-Sequence Intubation

1. Preparation of equipment and supplies
2. Preoxygenation
3. Sedation to decrease anxiety
4. Premedication to mitigate adverse effects: vecuronium bromide (1 mg) to prevent defasciculations, lidocaine (1.5 mg/kg) to prevent increased ICP with TBI
5. Cricoid pressure
6. Administration of paralytic agent: succinylcholine (1.0–1.5 mg/kg), vecuronium bromide (0.6–1.2 mg/kg) if succinylcholine contraindicated
7. Intubation
8. Confirmation of tube position by auscultation and capnography
9. Securing of airway
10. Chest x-ray to confirm optimal tube position

ICP = intracranial pressure; TBI = traumatic brain injury.

primarily by a rise in lactic acid production secondary to tissue hypoxia and usually resolves when the volume deficit has been corrected. Administration of sodium bicarbonate may cause a leftward shift in the oxyhemoglobin dissociation curve, reducing tissue oxygen extraction, and it may worsen intracellular acidosis caused by carbon dioxide production. On the other hand, adrenergic receptors may become desensitized with protracted acidosis. Studies indicate that vasopressin may be more effective than epinephrine as hemorrhagic shock approaches irreversibility. Bicarbonate infusion, therefore, should be limited to persons with protracted shock.

Hypocalcemia caused by citrate binding of ionized calcium does not occur until the blood transfusion rate exceeds 100 mL/min (1 U/5 min). Decreased serum levels of ionized calcium depress myocardial function before impairing coagulation. Calcium gluconate (10 mg/kg IV) should be reserved for cases in which there is electrocardiographic (ECG) evidence of QT interval prolongation or, in rare instances, for cases of unexplained hypotension during massive transfusion.

EVALUATION AND CONTINUED RESUSCITATION

Identification of Hemodynamic Instability

Recognizing the presence of shock and assessing its severity are key factors in early decision making. During the initial ABCs, palpation for the presence of pulses can be used to generate an estimate of systolic blood pressure (SBP). In general, a radial pulse is detected when SBP is higher than 80 mm Hg, a femoral pulse when SBP is above 70 mm Hg, and a carotid pulse when SBP exceeds 60 mm Hg. The initial blood pressure (BP) measurement should be made with a manual cuff; automatic cuff BP measurement machines may overestimate SBP in hypovolemic trauma patients.¹⁷ An SBP lower than 90 mm Hg (or an age-adjusted decrease in SBP that exceeds 30 mm Hg) in conjunction with an HR higher than 130 beats/min is generally considered indicative of major shock. Most patients, however, especially young ones, can compensate for hypovolemia and maintain a normal BP even in the face of significant ongoing hemorrhage. It should be kept in mind that because acute massive blood loss may paradoxically trigger a vagal-mediated bradycardia, the traditional inverse correlation between increased HR and reduced effective blood volume may not hold in the early resuscitation period.¹⁸ The initial hemoglobin level is notoriously misleading, either because the patient has not yet been volume loaded or because there has not been sufficient time for influx of interstitial fluid into the intravascular space. It is more informative to measure the hemoglobin level again after initial volume loading for purposes of comparison; a decrease greater than 2 g/dL should be grounds for concern.

The size of the base deficit can be a useful measure of the depth of hemorrhagic shock.¹⁹ Whether the base deficit is persisting or declining is more important than its absolute

value, but generally a base deficit greater than 8 mEq/L is indicative of severe shock. Measurement of central venous pressure (CVP) is helpful in identifying severe hypovolemia, and serial CVP measurements may be helpful to assess volume loading, but the correlation between circulating blood volume and CVP value is relatively poor.²⁰ Although arterial lines are of limited value in initial ED management, they become increasingly useful as time passes. The end points of initial resuscitation during the time of critical diagnostic testing and triage are as follows: (1) SBP higher than 90 mm Hg, (2) HR lower than 120 beats/min, (3) hemoglobin concentration equal to or greater than 10 g/dL, and (4) CVP equal to or greater than 10 cm H₂O.²¹

Management of Nonresponsive Unstable Patients

Shock that persists despite initial volume loading may derive from severe hypovolemia, cardiogenic causes, or neurogenic causes. Given that neurogenic shock is fairly well tolerated, the key concern at this point is to quickly distinguish hypovolemic shock from cardiogenic shock because cardiogenic shock may necessitate immediate ED intervention. This distinction can usually be made by measuring CVP in conjunction with physical examination. In hypovolemic shock, CVP is generally less than 5 mm Hg, whereas in clinically significant cardiogenic shock, CVP usually exceeds 20 mm Hg.

The differential diagnosis of traumatic cardiogenic shock depends on the mechanism of injury and may include (1) tension pneumothorax, (2) pericardial tamponade, (3) myocardial contusion, and (4) air embolism. Telltale physical signs may be difficult to discern in a noisy ED, especially when compounded by persistent hypovolemia. Timely diagnosis requires a high index of suspicion. Tension pneumothorax, the most common cause of cardiogenic shock in both blunt and penetrating trauma, is often first confirmed with emergency chest tube placement [see Figure 2].

In traumatic pericardial tamponade, the classic components of the Beck triad (hypotension, muffled heart sounds, and jugular venous distention) are frequently absent, and pulsus paradoxus is rarely detectable. ED ultrasonography is the first test employed by trauma surgeons in patients with high-risk penetrating wounds.²² However, the ultrasonogram may appear normal, with clotted blood in the pericardium, and CVP measurement is a helpful addition. Occasionally, a blunt trauma patient can be salvaged through timely diagnosis of a blunt atrial tear.

Myocardial contusion should be suspected in any blunt trauma patient with unexplained cardiogenic shock or persistent arrhythmia. ECG changes and elevated troponin levels are usually nonspecific.^{23,24} Fundamental interventions include correction of acidosis, hypoxia, and electrolyte abnormalities; judicious administration of fluid; and pharmacologic suppression of life-threatening arrhythmias.

Bronchovenous air embolism into the left atrium from a pulmonary laceration typically occurs after penetrating trauma and is more common than is generally recognized.²⁵

Figure 2 In acute trauma, a tube thoracostomy is performed through the fourth or fifth interspace at the midaxillary line, well above the diaphragm (a). A short subcutaneous tunnel is fashioned over the superior edge of the rib, and the overlying fascia and intercostal muscle are divided sharply. The pleural space is entered by incising the intercostal muscle and the pleura with a heavy scissors (b). A gloved finger is then inserted to confirm penetration of the thoracic cavity and to free up intrapleural adhesions (c). A large-bore tube (36 French) is directed posteriorly toward the pleural apex; the proximal port must be well inside the chest (d). The tube is then secured to the chest wall with No. 5 braided polyethylene suture and connected to a standard collection apparatus.

Hemodynamic instability develops after positive pressure ventilation is initiated as air is forced from the pulmonary bronchioles into the adjacent open pulmonary veins and, ultimately, into the coronary arteries. ED thoracotomy is essential for pulmonary hilar cross-clamping, air aspiration from the left ventricle, and cardiac massage. The patient is then transferred to the operating room (OR) for definitive management of the pulmonary lesion before the hilar clamp is released.

ED thoracotomy is an integral part of the initial management of the patient who arrives in extremis and deteriorates to imminent cardiac arrest [see Figure 3].²⁶ The physiologic rationale is to minimize the duration of profound shock. ED thoracotomy permits (1) release of pericardial tamponade, (2) internal cardiac massage, (3) cross-clamping of the descending thoracic aorta to enhance coronary and cerebral perfusion and to reduce subdiaphragmatic bleeding, and (4) control of intrathoracic blood loss. Internal cardiac massage should be done bimanually; otherwise, a forceful thumb may rupture the relatively thin right ventricle as it becomes distended. When blood volume is depleted or pericardial tamponade is present, closed-chest compression is ineffective in maintaining systemic blood flow, whereas open cardiac massage maintains coronary and cerebral perfusion for as long as half an hour. Adjunctive thoracic aorta occlusion

enhances both coronary and cerebral perfusion by maintaining aortic diastolic pressure and increasing carotid systolic pressure. Aortic cross-clamping also decreases subdiaphragmatic bleeding in the event of associated abdominal injury. These benefits are obtained at the expense of increased myocardial oxygen demand and poor perfusion of the lower torso. Clinical experience suggests that 30 minutes is the limit for prevention of splanchnic ischemic sequelae. The possibility of patient salvage is largely determined by the mechanism of injury, as well as by the patient's condition at the time of thoracotomy. Success rates approach 50% in patients arriving in shock from a penetrating cardiac wound and 20% in patients with penetrating wounds as a whole. On the other hand, patient outcome is dismal when ED thoracotomy is performed in the setting of blunt trauma; it is now considered futile in patients lacking cardiac activity. Ventricular lacerations of the heart are repaired with pledgeted horizontal mattress sutures, whereas atrial injuries are controlled with a partially occluding vascular clamp and repaired with a continuous suture [see Figure 4]. Small left ventricular wounds can be closed without pledgets. For large ventricular wounds, skin staples are an alternative means for rapid closure. Extensive injuries to the lung with ongoing major hemorrhage may require temporary hilar clamping to enable transport to the OR.

Figure 3 For pericardiocentesis, an 18-gauge spinal needle is inserted at the left xiphoid-costal junction and inserted toward the inferior tip of the left scapula (angled 45° to the patient's right and 45° from the chest wall). The needle is advanced until blood or air is encountered; a "pop" may be appreciated as the needle tip traverses the pericardium. If air is withdrawn, the needle tip should be directed more toward the patient's midline. If blood is withdrawn, 50 mL should be aspirated and injected onto a sheet so that it can be inspected for clots. As a rule, intraventricular blood will clot, whereas defibrinated pericardial blood will not clot.

SECONDARY SURVEY WITH DEFINITIVE DIAGNOSIS AND TRIAGE DECISIONS

Fortunately, most acutely injured patients arriving in shock can be rendered

hemodynamically stable enough to undergo a secondary survey. Diagnosis and treatment proceed simultaneously. Prioritization is imperative and is governed by the initial severity of shock and its response to ongoing resuscitation [see Table 4].²⁷ Easily correctable life-threatening injuries should be addressed first before a search is made for occult trauma. Prioritization is also guided by the mechanism of injury. Penetrating trauma typically results in a localized injury, whereas blunt trauma frequently results in multiple injuries involving several body regions. When hemodynamic instability recurs, its cause must be identified and corrected promptly.

The length of time spent in the ED, the decision for urgent operation, and the ordering of special radiologic studies are critical decisions that must take into account the mechanism of injury, the severity of shock, and the availability of a staffed OR. A patient in refractory shock with a central abdominal gunshot wound (GSW), for example, clearly should be transported to the OR in a matter of minutes, but the management of a previously unstable victim of a motor vehicle crash who has a positive abdominal ultrasonogram combined with altered mental status, a widened mediastinum on chest x-ray, and an unstable pelvic fracture requires a far more complex decision. In general, however, when priorities conflict, the safest arena for managing critically injured patients is the OR.

Penetrating Trauma

Systematic assessment The secondary survey is more focused in cases of penetrating trauma, but the most common problem error is failure to identify multiple injuries. The priorities are (1) to identify all of the wounds, (2) to decide whether an urgent operation is indicated, and (3) to determine whether additional testing is needed to assist with intraoperative management. The decision-making process is driven by hemodynamic stability and the location of the wounds. Efforts should focus not on resuscitating the patient until vital signs are normal but, rather, on obtaining adequate IV access, ensuring that blood products are available, and notifying the OR. Hemodynamically unstable patients should be rapidly sent to the OR with minimal testing. The most valuable tests are plain x-rays to determine missile trajectory.

Neck Patients who have an obvious life-threatening penetrating injury (e.g., a gurgling wound, pulsatile bleeding, or a compromised airway) or are in severe shock should undergo operation promptly. ED management should be limited to airway control, external compression to control bleeding, IV access, and chest x-ray. A neurologic examination should be performed and documented in the event of a spine or carotid artery injury.

Management of hemodynamically stable patients without obvious injury is selective.²⁸ Patients with zone I wounds should undergo computed tomographic angiography (CTA) scanning or angiography to rule out occult vascular injuries. Alert patients with zone II injuries but without significant hematoma, crepitation, dysphonia, or dysphagia may be managed expectantly.²⁹ The exception is a transverse GSW where CT scanning is usually done because of the high risk of an occult injury. Symptomatic patients with zone III injuries should undergo CTA scanning or angiography to assess for arterial injury that may warrant angioembolization.³⁰

Figure 4 (a) A left anterolateral thoracotomy is performed through the fifth intercostal space. (b) The lung is reflected superiorly for placement of a Satinsky vascular clamp on the descending thoracic aorta. A pericardiotomy is performed with scissors anterior to the phrenic nerve. (c) A so-called butterfly extension across the sternum creates a bilateral anterolateral thoracotomy, providing access to both thoracic cavities and to the pulmonary hila, the heart, and the proximal great vessels.

Chest In unstable patients with thoracic injuries, a chest tube should be placed into the wounded hemithorax, followed by a chest x-ray to confirm tube placement, lung expansion, hemothorax evacuation, and the presence of foreign bodies. If a cardiac wound is suspected, ED ultra-

sonography should be performed.²² Persistent instability without evidence of intrathoracic bleeding or pericardial tamponade should raise the suspicion of intra-abdominal bleeding. Occasionally, a thoracic spinal cord injury contributes to hemodynamic instability.

The challenge in this setting is to quickly identify those patients who require an urgent operation. Patients with ultrasonographically documented hemopericardium and persistent tachycardia should undergo pericardiocentesis to relieve any ongoing subendocardial ischemia even if the SBP is normal, and a pigtailed catheter is inserted for repeated aspiration during transport to the OR [see Figure 5]. Patients who exhibit persistent signs of pericardial tamponade (e.g., CVP > 20 mm Hg) despite negative results from ultrasonography should be transported to the OR for creation of a subxiphoid pericardial window. If the patient is in extremis or deteriorates suddenly, ED thoracotomy should be performed promptly [see Figure 3]. Most patients diagnosed with intrathoracic bleeding outside the pericardium stabilize after tube thoracostomy and modest volume loading. Urgent thoracotomy is indicated for (1) so-called caked hemothorax [see Figure 6], (2) an initial chest tube output higher than 20 mL/kg, (3) a persistent output higher than 3 mL/kg/hr

Table 4 Hemodynamic Instability Score²⁷

Grade 0: No significant hypotension (systolic blood pressure < 90 mm Hg) or serious tachycardia (heart rate > 130)
Grade 1: Hypotension or tachycardia by report but none recorded in emergency department
Grade 2: Hypotension or tachycardia responsive to initial volume loading with no ongoing fluid or PRBC requirement
Grade 3: Hypotension or tachycardia responsive to initial volume loading with modest ongoing fluid (< 250 mL/hr) or PRBC requirement
Grade 4: Hypotension or tachycardia only responsive to > 2 liters of volume loading and the need for vigorous ongoing fluid infusion (> 250 mL/hr) and/or PRBC transfusion
Grade 5: Hypotension unresponsive to fluid and/or PRBC transfusion

PRBC = packed red blood cell.

Figure 5 (a) A Satinsky vascular clamp is used to control arterial and major vessel injuries while they are closed with a running suture. (b) For wounds close to coronary arteries, horizontal mattress sutures should be used to spare the arteries. (c) Small wounds to the thick left ventricle can be closed with interrupted simple sutures. (d) Larger wounds should be closed using pledgets; staple closure may be preferred for larger ventricular wounds.

for 3 consecutive hours, or (4) a 12-hour output exceeding 30 mL/kg. Patients with an initial chest tube output higher than 10 mL/kg should be closely observed for hemodynamic instability in the intensive care unit (ICU). Abrupt cessation of chest tube output may be deceptive; if hypotension persists or recurs, a second chest tube should be inserted and another chest x-ray obtained.³¹

Patients with large air leaks, massive subcutaneous emphysema, or a persistent pneumothorax should undergo bronchoscopy to exclude a tracheobronchial injury. Patients with transmediastinal GSWs or penetrating wounds close to the great vessels should undergo CT scanning, and angiography should be done if the trajectory delineated on the CT scan is in proximity to a major artery.³²

Lower chest Wounds located below the nipples anteriorly or the tips of the scapulas posteriorly may penetrate the diaphragm and cause significant intra-abdominal or retroperitoneal injuries. Such penetration occurs in 10% of stab wounds and 30% of GSWs.³³ If the patient is unstable, tube thoracostomy, chest x-ray, and abdominal ultrasonography

are indicated. If instability persists, the patient should be transported to the OR. If the patient stabilizes after tube thoracostomy, additional testing must be done to exclude associated injuries. Diagnostic peritoneal lavage (DPL) is a good screening test for intra-abdominal injuries. The red blood cell (RBC) threshold for OR interventions to rule out diaphragmatic injuries is lowered because the injury may not bleed substantially.³⁴ Thoracoscopy is performed for RBC counts between 1,000 and 10,000/ μ L and laparoscopy or laparotomy is performed for RBC counts greater than 10,000/ μ L. Left-sided penetrating injuries should be pursued more aggressively because of the increased risk of delayed visceral herniation. CT scanning may assist in diagnosing occult retroperitoneal injuries but is not reliable for excluding penetrating diaphragmatic injuries.

Anterior abdomen Unstable patients should be transported to the OR with minimal resuscitation and testing. Biplanar abdominal x-rays are often helpful in clarifying bullet trajectories; entrance and exit wounds should be

Figure 6 An emergency department chest x-ray shows a massive hemothorax. If the chest tube fails to evacuate the blood, this is a so-called caked hemothorax, which is an indication for emergency thoracotomy in the operating room.

marked with radiopaque objects. Management of stable patients depends on the mechanism of injury. Although there is some enthusiasm for selective management of GSWs, laparotomy is generally recommended for GSWs that violate the peritoneal cavity.³⁵ CT scanning or laparoscopy is indicated for suspicious tangential GSWs. Laparotomy is indicated in patients with overt peritonitis after a stab wound. In other patients, the stab wound should be explored. If there is no violation of the anterior fascia, the patient can safely be discharged. If the fascia is violated, the patient should be admitted for serial clinical assessments.³⁶

Retroperitoneal structures Unstable patients with injuries to the flank, the back, or the pelvis should undergo immediate laparotomy. Stable patients are difficult to evaluate. With the exception of blood on rectal examination, the findings from physical examination are unreliable. Gross hematuria is indicative of bladder or kidney injury. Triple-contrast CT scanning may be helpful in patients with high-risk wounds.³⁷ Most retroperitoneal colon injuries are identified on the basis of extraluminal gas or fluid rather than of contrast extravasation. Sigmoidoscopy should be performed if a rectal injury is suspected. High-risk wounds should be explored to ensure that retroperitoneal colon injuries are not missed; delayed diagnosis is associated with significant morbidity.

Extremities Unstable patients with isolated penetrating injuries to the extremities should be managed with external compression to control bleeding. Blind clamping for vascular injuries should not be done because of injury risk to adjacent nerves. IV access with modest volume loading, and prompt triage to the OR for exploration and definitive treatment. Recent war experience indicates that tourniquet use was a valuable adjunct in saving lives in the setting of explosions that caused mangled or amputated extremities; however, the follow-up studies related to limb morbidity were limited.³⁸ How this practice transcends into civilian trauma is conjectural, but it is important to emphasize that the inappropriate

use of tourniquets can cause considerable harm. It is important to note that although extremity injuries are common in civilian trauma, death from extremity exsanguination is rare.

Management of stable patients with penetrating extremity injuries begins with a search for “hard” signs of arterial injury (e.g., an expanding or pulsatile hematoma, absent distal pulses, a palpable thrill, an audible bruit, or signs of distal ischemia). The presence of any of these hard signs prompts further evaluation. If signs of distal ischemia exist, the patient should be taken to the OR, where on-table angiography is performed to identify the injury site. If knowledge of the patient’s specific vascular anatomy is needed and no signs of ischemia exist, a formal angiogram is reasonable. If “soft” signs (i.e., a history of arterial bleeding prior to ED admission, wound proximity to an artery, small nonpulsatile hematoma over the artery, nerve deficit originating in a nerve adjacent to the artery) of vascular injury are present, distal blood pressures should be measured in the injured extremity, the contralateral extremity. If the ratio of the BP in the injured extremity to that in the contralateral extremity is 0.90 or higher, arterial injury is virtually excluded and no additional testing is needed. These patients can be discharged from the ED but should follow up in the outpatient clinic because a small percentage will eventually come to operation as the original undetected injury progresses rather than heals. These ratios are not, however, reliable for excluding arterial injuries in the axilla or the groin. Furthermore, the presence of a “good” Doppler signal does not exclude an arterial injury.

Blunt Trauma

Systematic assessment The goal is to identify all potentially life- and limb-threatening injuries. A comprehensive assessment is crucial to facilitate triage from the ED to the OR, the CT scanning suite, the interventional radiology suite, or the ICU. The details of the patient’s medical history, as well as the details specifically related to the injury, are critical. The prehospital emergency medical technicians are encouraged to provide a comprehensive account of the event and a thorough patient assessment. A minimal review of the patient’s medical history should include preexisting medical illnesses, current medications (especially anticoagulation status in the elderly), allergies, tetanus immunization status, and the time of the last meal.³⁹ A helpful method to recall this list is the ATLS AMPLE: Allergies, Medications, Past illness, Last meal and Events/Environment. A rapid, systematic physical examination is done, literally from head to toe. Patients are completely disrobed and, once spinal injury is excluded, are rolled from side to side so that the back and the flanks can be inspected. A rectal examination is done to look for blood and to evaluate sphincter tone; the perineum and the axillae are inspected; and neurologic function and peripheral pulses are documented.

The cervical spine is rigidly immobilized, and long-bone fractures are splinted to minimize pain, blood loss, and soft tissue damage. Insertion of a gastric tube decompresses the stomach and reduces the risk of pulmonary aspiration; because maxillofacial injury may provide a pathway into the cranial vault,⁴⁰ the tube should be placed orally when midfacial fractures are present. Blood in the gastric aspirate may be the only sign of an otherwise occult injury to the stomach or the duodenum.

Placement of a Foley catheter empties the bladder, discloses hematuria, and permits the physician to monitor urinary output. The Foley catheter should not, however, be inserted until abdominal ultrasonography is completed, and it should not be placed on an urgent basis in male patients with suspected urethral injuries (i.e., those with blood at the meatus, a perineal hematoma, a high-riding prostate, or an extensively displaced anterior pelvic fracture). If urethral injury is suspected, a retrograde urethrogram, followed by a cystogram (to exclude bladder injury), is obtained, prioritized in accordance with the given setting. In females, the urethra is shorter and better protected and thus is rarely injured.

Routine x-rays performed simultaneously with the ABCs include anteroposterior chest and pelvic films. CT scanning has virtually replaced plain x-rays for diagnosing potential spinal injuries. Once life-threatening injuries have been addressed, x-rays of extremities with suspected fractures (including the joint above and the joint below) should also be obtained, but preferably with guidance from an orthopedic surgeon.

Given that trauma victims are uniquely susceptible to hypothermia, a rectal or bladder temperature probe is essential in those who have been exposed to a cold environment or who require massive volume replacement. A core temperature reading lower than 32°C (89.6°F) should be confirmed with an esophageal probe, and rewarming measures appropriate for the degree of hypothermia should be initiated. Tetanus prophylaxis is routine. Systemic antibiotics should be withheld until a specific indication arises.⁴¹ An ECG is obtained after blunt chest trauma, and an ABG analysis is done in select patients to confirm adequate ventilation and metabolic balance. In patients with evidence of significant hypovolemia, a blood sample should be sent for blood-group typing and coagulation studies.

Rapid hemorrhage control Blunt trauma patients who arrive in shock and remain hemodynamically unstable pose difficult triage decisions. Initial screening must be directed at identifying life-threatening bleeding that necessitates immediate OR intervention. Most hospitals do not have an interventional radiology suite immediately available; early notification is crucial in assembling the team. At our institutions, after normal working hours, this process consumes more than 1 hour.

Initial screening focuses on the chest, the abdomen, and the pelvis. A chest x-ray is the most reliable screening test for intrathoracic bleeding; it also confirms the location of endotracheal, nasogastric, and thoracostomy tubes, as well as that of the central venous catheter. The presence of pleural fluid may be difficult to confirm on a supine chest x-ray: 1 L of blood may produce only a hazy appearance in a hemithorax. Hemothoraces should be drained promptly via tube thoracostomy [see Figure 2]. Continued bleeding must be monitored carefully by measuring chest tube output, obtaining serial chest films to detect retained intrapleural blood, and observing vital signs. The criteria used to decide when thoracotomy is indicated are similar to those used in cases of penetrating trauma, but far fewer blunt trauma patients meet these criteria, and intrathoracic bleeding is rarely a reason for immediate OR triage.

The abdomen is notoriously difficult to evaluate and is much more likely than the chest to harbor occult life-threatening bleeding. The peritoneal cavity may sequester as much as 3 L of blood with only minimal abdominal distention. Head injury or intoxication frequently alters the patient's response to acute injury, and pain from associated fractures may overshadow peritoneal irritation secondary to bleeding. Ultrasonography [see Figure 7 and Figure 8] is the most rapid method of identifying free blood, but it may yield false negative results in as many as 15% of patients on initial examination.⁴² Diagnostic peritoneal aspirate (DPA) [see Figure 9] remains the most reliable method of identifying significant intraperitoneal hemorrhage in patients with life-threatening bleeding.⁴³ In patients presenting in high-grade shock, a grossly positive aspirate (> 10 mL of blood) warrants emergency laparotomy.²⁷

Assessment of bony stability by means of physical examination and plain films of the pelvis is crucial for the early identification of major pelvic fractures. Life-threatening hemorrhage occurs most commonly with fracture patterns involving the posterior columns [see Figure 10]. Appropriate initial management of unstable patients who have a high-risk pelvic fracture on the initial pelvic x-ray includes blood volume replacement (including early blood and FFP) and

Figure 7 Shown are four transducer positions in the FAST (focused assessment with sonographic evaluation of the trauma patient): (1) pericardial area, (2) right upper quadrant, (3) left upper quadrant, and (4) pelvis.

Figure 8 (a) A sagittal ultrasound image of liver, kidney, and diaphragm yields normal findings. (b) A sagittal ultrasound image of the right upper quadrant shows blood between the liver and kidney and between the liver and diaphragm.

application of a pelvic binder; wrapping with a sheet is also effective [see Figure 11].

The next step is to evaluate the response to initial resuscitation and then perform ultrasonography or DPA to determine whether significant intra-abdominal bleeding is present.^{44,45} An unstable patient with clearly positive findings from ultrasonography or DPA should undergo laparotomy because of the high probability of major hepatic, splenic, or mesenteric bleeding. If there is a large pelvic hematoma at the time of laparotomy and the patient is unstable, extraperitoneal pelvic packing should be done [see Figure 12].⁴⁶ The role of pelvic packing versus angioembolization is controversial, but these modalities should be viewed as complementary.⁴⁷

Fast-track CT scanning to refine triage In unstable patients who respond to initial interventions, the priorities are to (1) identify and quantitate ongoing sources of bleeding; (2) identify TBI, especially in those patients who require immediate craniotomy; and (3) identify any other injuries that call for urgent intervention (e.g., thoracic aortic injury

[TAI]) or special precautions (e.g., spine fractures). With the widespread availability of multidetector CT scanners in proximity to the ED, rapid whole-body imaging is now feasible, permitting accurate triage for these competing priorities.⁴⁸ The decision to order CT scanning is made early, while the ABCs are being addressed and ultrasonography and initial plain x-rays are being performed, and depends on the age of the patient, any obvious injuries identified, and the patient's hemodynamic stability. The decision is less clear-cut in the common situation in which a previously unstable patient has a positive abdominal ultrasonogram. The key issue here is which injuries identified by CT scanning would alter the decision to perform an urgent laparotomy. Some institutions make much larger "cuts" so that the scan can be done faster, and the final CT scans lacks the detail needed to describe injuries well and may miss injuries in the abdomen and pelvis.

Identification of abdominal injuries The decision to perform an urgent laparotomy in a patient with a positive ultrasonogram depends on the patient's hemodynamic stability. A CT scan can be helpful in refining triage by identifying extravasation of IV contrast (i.e., a blush) and in diagnosing hollow viscus injuries. A blush should prompt consideration of angiography. Early angiography is a helpful adjunct in managing liver and kidney injuries, although its role in managing acute splenic injuries remains to be established.^{27,49,50} Hollow viscus injury is notoriously difficult to diagnose; extravasation of oral contrast is rare.^{51,52} When all signs (e.g., unexplained free fluid, bowel wall thickening, mesenteric streaking, and free air) are considered, however, the sensitivity of CT in making the diagnosis approaches 90%. In questionable cases of hollow viscus injury in stabilized patients, we advocate delayed DPL to search for elevations in WBC count, amylase level, and alkaline phosphatase level. Pancreatic injury is also poorly defined on the initial CT scan. A rising lipase warrants repeat CT scanning (and consideration for endoscopic retrograde cholangiopancreatography or magnetic retrograde cholangiopancreatography).⁵³

Identification of TBI Approximately 20% of blunt trauma patients who arrive in shock have a TBI.⁵⁴ During the initial evaluation, it is important to identify TBI patients who might benefit from an emergency craniotomy. The neurologic examination is of utmost importance. The initial Glasgow Coma Scale (GCS) score in the field should be confirmed with prehospital personnel, and short-acting sedatives or paralytics should be given sparingly. A GCS score lower than 8 and a lateralizing neurologic examination indicate a significant risk that emergency craniotomy will be needed and, therefore, justify obtaining a CT scan of the head if hemodynamic stability permits.^{55,56}

Identification of TAI Initial plain films should be examined for evidence of TAI. We use the overpenetrated mediastinal view and specifically look for evidence of a mediastinal hematoma. In the multi-institutional study from the American Association for the Surgery of Trauma (AAST) however, 7% of patients with TAI had a normal ED chest x-ray. We therefore obtain a chest CT scan on the basis

Figure 9 Illustrated here is the semiopen technique for peritoneal lavage. A 3 to 4 cm incision is made over the infraumbilical ring, and the linea alba is incised vertically for 1 cm. The fascial edges are grasped with towel clips and elevated. A standard peritoneal dialysis catheter is introduced into the peritoneum at a 45° angle and then advanced into the pelvis without use of the trocar. If 10 mL of gross blood is aspirated, the study is considered to be positive. Otherwise, 1 L of normal saline (10 mL/kg for children) is infused. The lavage fluid is retrieved by gravity siphonage; the empty saline bag is dropped to the floor. Ultrasonography is helpful for confirming intraperitoneal fluid infusion. A 50 mL sample of the fluid is submitted for laboratory analysis.

of the mechanism of injury.⁵⁷ CT scanning has replaced angiography for the diagnosis of TAI. An occasional angiogram is done to confirm the diagnosis of great vessel injury or to clarify the vascular anatomy before thoracotomy.

The management of TAI has changed markedly over the past decade. Traditionally, a diagnosis of TAI mandated urgent thoracotomy. Currently, however, antihypertensive therapy and ICU monitoring allow delayed repair in patients with significant associated injuries.⁵⁸ Additionally, endovascular stenting has become preferred over open repair for favorable lesions.⁵⁹

Identification of limb ischemia The absence of distal pulses in a fractured or dislocated extremity should be addressed urgently. Fractures and dislocations should be reduced, and the extremity should be closely examined for signs of ischemia.⁶⁰ Distal SBP measurements comparing injured limbs with noninjured limbs (i.e., the ankle-ankle index [AAI] or the ankle-brachial index [ABI]) should be obtained. If the ABI or AAI is less than 0.90 after reduction, CTA should be performed to exclude the presence of an arterial injury.^{61,62} A pulseless extremity is best evaluated in the OR by means of on-table angiography.

Discussion

Prehospital Care

ADVANCED TRAUMA LIFE SUPPORT

The growing sophistication of EMS has expanded the scope of prehospital care, but the extent of prehospital

interventions remains a highly controversial issue.¹ In trauma, advocates of the so-called scoop-and-run philosophy argue that resuscitative efforts in the field unnecessarily delay provision of definitive care and have detrimental effects on physiology and survival when overzealously applied. At

Figure 10 Pelvic angiography with selective embolization may be an integral component in the early management of a major pelvic crush injury with continuing hemorrhage.

present, there is little evidence to support the use of ATLS in prehospital management of urban trauma patients. ATLS skills may be of value in rural areas where transport time exceeds 30 minutes, but, unfortunately, the limited volume of serious trauma in such areas makes it difficult to gain the experience necessary to maintain this expertise.

Prehospital Airway Management

The goal of initial resuscitation is to restore adequate oxygen delivery to vital organs. Efforts to improve tissue perfusion will be unproductive unless the oxygen content of the circulating blood is sufficient. Airway patency and maintenance of adequate ventilation are thus the initial priorities. However, intubation and positive pressure ventilation inhibit venous return to the heart and detrimentally decrease cardiac output in hypovolemic patients.⁶³ Furthermore, patients intubated in the field are often hyperventilated, and the resulting low P_{aCO_2} causes cerebral vasoconstriction. Routine end-tidal capnometry for TBI patients undergoing field intubation has been proposed as the standard of care for preventing excessive hyperventilation.² In addition, emergency airway control after blunt trauma should be performed with the assumption that an unstable cervical spine fracture exists until such injuries are excluded radiologically, but this policy does not preclude RSI. The current recommendation—oro-tracheal intubation with in-line manual stabilization of the head and neck—has proven safe. When oro-tracheal intubation fails, the laryngeal mask airway is a rapid, safe, and effective technique

Figure 11 Shown is the wrapping technique currently used for support of a mechanically unstable pelvic fracture.

for maintaining temporary airway control until definitive medical care becomes available.¹¹ For patients with extensive maxillofacial trauma that precludes oral intubation, cricothyrotomy has been the traditional alternative, but this procedure has some risks, particularly in children.

Prehospital Volume Resuscitation

A provocative 1994 clinical trial found that for hypotensive patients with penetrating torso injuries, survival improved when fluid resuscitation was delayed until surgical intervention

Figure 12 Preperitoneal pelvic packing (PPP) is performed through a 6 to 8 cm midline incision made from the pubic symphysis cephalad, with division of the midline fascia. The pelvic hematoma often dissects the preperitoneal and paravesical space down to the presacral region, facilitating PPP; alternatively, blunt digital dissection opens the preperitoneal space for packing. Three standard surgical laparotomy pads are placed on each side of the bladder, deep within the preperitoneal space, and the fascia is closed with O-PDS suture and the skin with staples.

had controlled the source of hemorrhage.³ A subsequent subset analysis, however, revealed that survival was improved only in patients who had sustained cardiac injuries, not in patients who had sustained major vascular, abdominal solid organ, or noncardiac thoracic injuries.⁶⁴ Although this clinical trial had some methodologic flaws, it was important because it emphasizes that source control of hemorrhage is an overriding priority in hemodynamically unstable patients.

Whether fluid resuscitation should be withheld until control of hemorrhage is achieved is doubtful; such an approach is clearly not the current standard of care. The critical issue is whether it is preferable to administer fluids to restore oxygen delivery to tissue, but potentially causing hemodilution and disruption of early hemostatic clots, or to withhold fluid resuscitation, prolonging cellular shock to the point where it may be irreversible by the time operative control is accomplished. At present, the rational compromise between these two extremes is hypotensive resuscitation with limited volume loading with the goal of maintaining SBP > 90 mm Hg.^{65,66} This approach is becoming the standard of care for penetrating trauma, but its application to blunt trauma is not as clear as 20% of patients with major torso trauma have a serious concomitant TBI and hypotension is a well-documented risk factor for poor outcomes with TBI.

Resuscitation with Hypertonic Saline

A report by Velasco and colleagues in 1980 spurred renewed research interest in hypertonic saline (HS).⁶⁷ Small-volume HS was shown to be as effective as large-volume crystalloids in expanding plasma volume and enhancing cardiac output in hemorrhagic shock in animals. Furthermore, HS increased perfusion of the microcirculation, presumably by selective arteriolar vasodilatation and by decreasing swelling of the endothelium. This improved microcirculation, however, could lead to increased bleeding. Consequently, HS was tested in animal models of uncontrolled hemorrhagic shock and was shown to increase bleeding, but mortality was model

dependent, and the best survival was obtained when HS was given with high-volume isotonic crystalloids. Additionally, the resuscitative effectiveness of HS was found to be enhanced by combination with dextran (hypertonic saline dextran [HSD]). In view of the small volume needed to achieve these effects, there was great interest in the use of HS in resuscitation in the field for both military and civilian use. From the late 1980s through the early 1990s, prospective randomized controlled trials (PRCTs) were performed.¹³ Individually, these trials found survival outcome to be inconsistently improved but did document that a bolus of HS is safe. Meta-analysis of these data suggests that HS is no better than standard-of-care isotonic crystalloid fluids.⁶⁸ Subgroup analysis of the data showed that the patients who benefited most from HSD were those who presented with shock and concomitant severe TBI. The results of this analysis agreed with laboratory data showing that in comparison with isotonic crystalloid, both HS and HSD raised cerebral perfusion pressure, lowered intracranial pressure, and reduced brain edema. However, one well-executed trial that tested HS for field resuscitation of TBI patients in shock did not demonstrate any benefits.⁶⁹

Recent laboratory studies have again renewed interest in the use of HS in early traumatic shock resuscitation. Numerous basic laboratory investigators have convincingly shown that HS resuscitation markedly decreases the inflammatory response (specifically neutrophil cytotoxicity) in animal models of hemorrhagic shock, ischemia/reperfusion, and sepsis. One very interesting clinical PRCT from Toronto showed that an immunomodulatory effect occurs in humans who are undergoing shock resuscitation.⁷⁰ The researchers showed that HS promotes a more balanced inflammatory response to hemorrhagic shock. This raises the possibility that, similar to observations made in experimental models, HS might also decrease the incidence and severity of post-traumatic acute respiratory distress syndrome (ARDS) and multiple organ failure (MOF). This hypothesis was tested in

a recent clinical PRCT from Harborview Medical Center in Seattle.⁷¹ The study was stopped for futility after the second interim analysis. Intent-to treat analysis demonstrated no significant difference in ARDS-free survival. Most recently, a National Institutes of Health (NIH)-sponsored Resuscitation Outcomes Consortium multicenter trial testing HS demonstrated similar disappointing results.⁷² This involved two parallel studies. The first (which enrolled trauma patients in shock with severe bleeding) was stopped in March 2009 because of safety concerns noted in an interim analysis. Although overall 28-day mortality was not different, more of the patients receiving HSD were dying earlier than those who received NS. The second study (which enrolled TBI patients) was stopped after interim analysis of 1,073 patients who were followed for 6 months and demonstrated no differences in outcomes. In summary, although the experimental data supporting HS resuscitation in the setting of traumatic shock with or without TBI are very compelling, HS resuscitation has been very extensively tested in the clinical setting for these indications, and there are no conclusive data to support its routine use.

ED Management

BLOOD VOLUME RESTITUTION

Traditional Crystalloid versus Colloid Debate

Since the early 1940s, restoration of blood volume has been embraced as a pivotal intervention in shock resuscitation; however, considerable controversy has persisted concerning optimal fluid to use.¹⁴ Plasma and serum were considered the best substitutes for whole blood and, in some cases, better than blood itself. This was the resuscitation strategy used in World War II, and renal failure was noted to be a major cause of late deaths in soldiers who survived shock resuscitation. Isotonic crystalloids became the standard of care in the late 1960s based on the laboratory work of Shires and colleagues and Dillon and colleagues, as well as others.^{73,74} Their basic concept was that during hemorrhagic shock, interstitial fluid is redistributed into both the intravascular and intracellular spaces; thus, large-volume resuscitation with isotonic crystalloids is needed to replenish losses from both the intravascular and interstitial spaces. These investigators empirically observed that optimal resuscitation to correct this extracellular fluid deficit required infusion of isotonic crystalloid fluid and shed blood in a ratio of three volumes of crystalloid to one of blood.⁷⁵

As a result of this experimental work, isotonic crystalloid fluids were used in the Vietnam conflict. For various reasons, mortality and acute renal failure decreased, but a new entity called “shock lung” emerged as a major cause of late deaths. This complication was soon described in civilian publications as ARDS and was shown to be the major source of morbidity and mortality in the ICU. The pathogenesis was not known, but controversy existed over whether ARDS was an iatrogenic complication of resuscitation with isotonic crystalloids.

Beginning in the mid-1970s, PRCTs were done to compare crystalloids with colloids in resuscitation, with pulmonary dysfunction as the primary end point. The results were conflicting and in large part were attributable to shortcomings

in study design (i.e., small numbers of patients, heterogeneous populations, and different resuscitation end points and sodium loads), as well as difficulty in defining pulmonary dysfunction. These data have been assessed by meta-analysis, and no difference in the incidence of pulmonary dysfunction has been found.⁷⁶ However, when mortality is used as the end point and the data are subgrouped, the use of crystalloids in trauma patients is associated with improved survival.

The same subgroup analysis was done in the most recent SAFE trial, and again the use of isotonic crystalloids compared to albumin in trauma patients was associated with improved survival.⁷⁷ Although these subgroup data are not definitive, they are consistent with the early laboratory work and do support the current use of crystalloids in US trauma centers. Additionally, it has been difficult to justify the standard use of colloid solutions because they are considerably more expensive than crystalloid solutions. The relative costs per 500 cc of intravascular volume expansion is \$130 for albumin 25%, \$88 for albumin 5%, \$78 for plasmonate 5%, \$20 for dextran 70%, \$20 for hetastarch 6%, and 17% for Hextend compared to \$3 for LR solution.

Choice of Crystalloid

The selection of a crystalloid engenders less controversy than the choice between crystalloid and colloid. Although newer formulations (e.g., Ringer ethyl pyruvate) are being tested clinically,⁷⁸ NS and LR solution remain the most commonly used fluids. In theory, LR solution is preferable to NS because it provides a better buffer for metabolic acidosis, but to date, investigators have not documented any important differences in outcome. One laboratory study found that NS and LR solution were equivalent in the setting of moderate hemorrhagic shock but that, in the setting of massive hemorrhage, NS was associated with greater physiologic derangement (e.g., hyperchloremic acidosis) and higher mortality.⁷⁹ Clinical experience confirms the adverse effects of iatrogenic hyperchloremia.⁸⁰ NS is preferred, however, when blood is being transfused simultaneously. There is some concern that the calcium in LR solution could exceed the chelating capabilities of the citrate in the stored blood, resulting in the formation of clots that could enter the circulation and compromise the microcirculation, although there is no objective clinical evidence to substantiate these concerns.

Transfusion Trigger

Banked RBCs have been widely available since World War II, but the indications for administration continue to be debated.¹⁴ Animals with hemorrhagic shock were shown to have improved survival with hemoglobin concentration ([Hb]) maintained in the range of 12 to 13 g/dL. However, animal models of isovolemic hemodilution demonstrated that the optimum [Hb] for maintaining systemic oxygen delivery (DO₂) is 10 g/dL, but in healthy human volunteers, isovolemic hemodilution is tolerated at concentrations as low as 5 g/dL. Until recently, clinical studies in critically ill patients concluded that 10 g/dL hemoglobin was optimum for shock resuscitation, but more recent consensus panels have judged that a lower concentration is adequate. The American Society of Anesthesiologists recommends maintaining hemoglobin at greater than 6 g/dL, whereas the NIH recommends a concentration of greater than 7 g/dL. A PRCT has shown

that ICU patients randomized to restrictive blood transfusions (transfuse if hemoglobin concentration is < 7 g/L and maintain between 7 and 9 g/dL) did as well and possibly better than patients who were liberally transfused (transfuse if < 10 g/dL and maintain between 10 and 12 g/dL).⁸¹ We and others have reported that transfusion of PRBCs is a strong risk factor, independent of shock severity, for bad outcomes (i.e., infections, MOF, and deaths) in trauma patients (a patient population most likely to benefit from PRBC transfusion).⁸² The observation that transfusion of PRBCs is associated with adverse outcomes has now been consistently observed across a broad spectrum of high-risk hospitalized patients.⁸³ The choice of transfusion trigger is dependent on the clinical scenario. During active shock resuscitation with ongoing bleeding, shooting for a higher hemoglobin level is preferred. Blood is a good volume expander and will limit isotonic crystalloid infusions, and the higher hemoglobin level provides a margin of safety. Once bleeding is controlled, the lower transfusion trigger should be used unless there is evidence of high oxygen extraction (i.e., SaO_2 minus mixed venous hemoglobin oxygen saturation $< 50\%$).

The adverse outcomes of PRBC transfusion are attributed to the age of stored RBCs. The concept of transfusion-related immunosuppression dates from the early 1970s with the observation that greater pretransplantation transfusion was associated with improved renal allograft survival. Subsequently, perioperative PRBC transfusion was associated with cell-mediated immunosuppression, tumor recurrence, and postoperative infections. The capacity of banked PRBCs to provoke neutrophil cytotoxicity is a key mechanism in MOF.⁸⁴ Focused clinical studies have shown that severely injured patients at high risk of MOF have circulating neutrophils that are primed for cytotoxicity within the first 6 hours after injury, increased expression of adhesion receptors, activation of p38 mitogen-activated protein kinase, and delayed apoptosis. The precise mechanisms linking PRBC transfusion and neutrophil priming remain to be established, but it is generally believed that passenger leukocytes accompanying RBCs in storage are important in the generation of proinflammatory agents that progressively increase from 14 to 42 days of storage. Some investigators have implicated cytokines (tumor necrosis factor, interleukin-1, interleukin-6, interleukin-8), but our focus has been on proinflammatory lipids presumably generated from the degradation of the RBC membrane. Although prestorage leukoreduction of PRBCs decreases the generation of cytokines, this process does not eliminate neutrophil priming. Another emerging concern regarding stored cells is that substantial shape changes and impaired deformability occur by the second week of storage and progress during further preservation. The effects of decreased deformability on microcirculation have been documented experimentally and include impaired tissue access and entrapment, resulting in microvascular obstruction.⁸⁵ These findings might account for the observation that blood transfusion failed to improve oxygen consumption in critically ill and injured patients and, in one study, appeared to induce splanchnic ischemia.^{86,87}

Blood Substitutes

As a consequence of the limited supply of stored blood and the recognition that transfusions contribute to adverse patient outcomes, there has been a resurgence of interest in blood

substitutes. Hemoglobin-based oxygen carriers (HBOCs) date back to 1933, when it was shown that hemolysates could transport oxygen in mammals. Unfortunately, when these solutions were infused into humans, they had excessively toxic effects (i.e., vasoconstriction, acute renal failure, and abdominal pain), which were attributed to stromal contamination.

Although the next generation of HBOCs were stroma-free, toxic effects persisted and were attributed to the instability of the hemoglobin tetramer, which spontaneously dissociates into dimers and monomers. The next generation of HBOC formulations focused on stabilizing the hemoglobin tetramer. One of these products, diaspirin cross-linked hemoglobin, was authorized for a phase III study in trauma patients.⁸⁸ However, the trial was prematurely stopped because of the unexpectedly high mortality in the treatment group (24 of 52 [46%] compared with 8 of 46 [17%] in the control group). Although this event was judged a major setback for clinical implementation of HBOCs, the product used had already been shown to increase pulmonary and systemic vascular resistance in animals. Tetrameric hemoglobin extravasates from the vascular space, binds nitric oxide within the vessel wall, and thereby results in unopposed vasoconstriction. This issue has been effectively addressed by polymerizing the hemoglobin tetramer.⁸⁹ The additional benefit of these larger moieties is that they exert less colloid osmotic activity, which means that a higher dose can be administered.

A further limitation of earlier HBOCs was that because of the loss of 2,3-diphosphoglycerate, oxygen affinity was greatly increased; the partial pressure of oxygen required to produce 50% saturation (P_{50}) decreased from the normal 26 mm Hg to 12 mm Hg. This problem was addressed by pyridoxylation of the hemoglobin tetramer, which raised the P_{50} to 29 mm Hg. One such polymerized hemoglobin solution has been tested extensively in phase I and phase II trials in trauma patients, where it proved to be safe and effective. A phase III prehospital trial has recently been completed where this polymerized hemoglobin solution appeared to provide equivalent outcomes to stored PRBCs.⁸⁹ Unfortunately, the Food and Drug Administration did not agree with the investigators' conclusions, thus apparently ending another chapter in the history of blood substitutes. A new generation of HBOCs is being developed, but, unfortunately, these will unlikely be available for clinical use in the next decade.

EARLY IDENTIFICATION OF NONRESPONDERS

BP and HR are the current standard-of-care monitors of shock resuscitation in the field and in the ED. Both, however, are insensitive markers of early compensated shock; alternative monitors are badly needed for assessing the adequacy of tissue perfusion with a view to avoiding both underresuscitation and overresuscitation. Near-infrared spectroscopy, a simple technique that monitors oxygen saturation in tissue, has been shown to track oxygen delivery reasonably well during shock resuscitation and has been tested as an ED monitor.⁹⁰ Transcutaneous oxygen tension monitoring and central venous oxygen saturation monitoring have also shown promising results in the ED environment.⁹¹

The challenge is to identify as early as possible those patients who are not responding to early interventions. Blind and aggressive volume loading in the hope of normalizing

BP and HR, without appropriate emphasis on control of hemorrhage, sets the stage for the so-called bloody vicious cycle [see Figure 13] or the abdominal compartment syndrome (ACS).⁹²

CONTROVERSIES IN POSTINJURY COAGULOPATHY

Most deaths in injured patients arriving to the hospital with major blood loss are attributable to progressive coagulopathy. Thus, identifying the patient at risk for coagulopathy and treating the factors associated with defective coagulation are integral to initial management. Factors predictive of severe coagulopathy include persistent hemorrhagic shock reflected by metabolic acidosis (base deficit [BD] > 14), refractory core hypothermia (< 34°C), and massive transfusion (> 10 U PRBC/6 hr). During the Vietnam war, coagulation abnormalities were recognized to be associated with prolonged shock and, ultimately, a poor prognosis. However, extensive prospective studies by the Puget Sound Blood Bank found a relatively poor correlation between prothrombin time (PT), partial thromboplastin time (PTT), and bleeding times with coagulation status in patients requiring massive transfusion.⁹³ Consequently, when whole blood transfusion was changed to blood component management, it was acknowledged that FFP should be given empirically with packed RBCs in patients anticipated to need a massive transfusion. Despite 40 years

of investigation, three interrelated areas of controversy exist: (1) the pathogenesis of the acute coagulopathy of trauma, (2) the optimal ratio of blood components to be administered empirically for resuscitation of the critically injured patients (i.e., damage control resuscitation), and (3) the end points for blood component management (i.e., goal-directed therapy).

ACUTE COAGULOPATHY OF TRAUMA

Recent work by Brohi and colleagues suggests that coagulopathy develops very early postinjury and that it is principally driven by thrombin binding to endothelial thrombomodulin resulting in activated protein C-mediated anticoagulation.⁹⁴ This acute coagulopathy appears to be related mechanistically to tissue ischemia from pronounced shock. Such a process may be teleologically protective by inducing an auto-anticoagulation state that prevents thrombosis in critical tissue beds during prolonged periods of low flow while exposed tissue factor is promoting clot formation at the injury site. An alternative hypothesis is that early clotting derangement is due to disseminated intravascular coagulation and fibrinolysis. The importance of this debate is the determination of whether the early coagulopathy following injury is attributable to clotting factor deficiency requiring immediate blood component replacement.

Figure 13 The so-called bloody vicious cycle is a syndrome that has a multifactorial pathogenesis. The usual manifestations include coagulopathy, hypothermia, and metabolic acidosis.⁹² FFP = fresh frozen plasma; RBC = red blood cell.

PREEMPTIVE BLOOD COMPONENT ADMINISTRATION

Although there is a general consensus that clotting factors should be administered concurrently with PRBCs in patients anticipated to require a massive transfusion, the optimal composition of these components remains unclear. For effective hemostasis, the conversion of prothrombin to thrombin requires factors XII, XI, IX, and VIII as well as activated factors X and V. FFP provides these factors and up to 400 mg of fibrinogen. Traditionally, FFP was prepared by isolating the plasma from the cellular components via centrifugation of whole blood within 8 hours of collection. With the advent of apheresis methods, most FFP is now platelet-rich plasma, which is then frozen. The hemostatic activity of most coagulation factors is maintained for long periods, although factors V and VIII decrease with thawing. For nearly 30 years, empiric transfusion of FFP has been recommended, but the ratio of FFP to RBC remains controversial. Early experimental work and subsequent clinical observations indicated that ratios of FFP to RBC $< 1:4$ were warranted to avoid factor deficiency, but platelets were not justified for initial RBC resuscitation. Recently, the military has promulgated a preemptive platelet to FFP to RBC ratio of 1:1:1 based on the argument that this represents the composition of shed whole blood.⁹⁵ A retrospective review of this policy appears to demonstrate a survival benefit in critically injured soldiers requiring massive transfusion. However, a more recent subanalysis suggests that this benefit may be primary in those with extensive blast injury. Furthermore, concurrent civilian data suggest that an FFP to RBC ratio of 1:2 to 1:3 may be adequate.⁹⁶ The rationale for preemptive platelet transfusion is similarly controversial. Clinical studies to date, including the extensive Puget Sound Blood Bank work, do not substantiate initial platelet repletion. The resolution of these ongoing debates requires a better understanding of the scientific basis for achieving postinjury hemostasis.

GOAL-DIRECTED HEMOSTATIC THERAPY

A recent paradigm shift to the cell-based concept of hemostasis underscores the need for a rapid comprehensive assessment of coagulation. Resurgent interest in thromboelastography (TEG) suggests that this technology may provide a real-time viscoelastic analysis of blood clotting that includes the interaction of the enzymatic cascade with platelets. Whole blood (0.35 mL) is placed in a rotating metal curette heated to 37°C. A piston is suspended in the sample, and the rotational motion is transferred to the piston as fibrin strands form between the wall of the curette and the piston. TEG assesses clot strength from the time of initial fibrin formation to clot retraction, ending in fibrinolysis. In contrast, the standard battery of coagulation studies (PT, PTT, and bleeding time) is based on isolated, static end points. Rapid TEG is further advantageous as the addition of tissue factor to the whole blood specimen stimulates a rapid reaction. The resulting coagulation tracing can be transmitted from the blood bank to the OR or surgical ICU, exhibiting a functional profile within 5 minutes of blood sampling. This point-of-care monitoring offers the possibility of goal-directed coagulation management, analyzing virtually in real time the impact of specific component administration. Experimental work and nonrandomized clinical studies thus far appear to support this concept.

ACS AND REVISITING THE CRYSTALLOID VERSUS COLLOID DEBATE

Unfortunately, the above-described PRCTs comparing crystalloid and colloid resuscitation were done long before the ACS had become recognized as an important clinical entity. ACS emerged as an epidemic in the mid-1990s in US level I trauma centers as a result of changes in a number of processes of care that started in the 1980s, including the following: (1) trauma system development, which triaged badly injured patients into high-volume centers with specialized shock trauma ICUs; (2) ATLS-endorsed high-volume isotonic crystalloids to achieve a normal BP as a standard of care for initial resuscitation; (3) damage control surgery allowed patients to survive who previously exsanguinated on the OR table; and (4) the widespread availability and use of pulmonary artery catheters to pursue goal-oriented resuscitation to supranormal levels of oxygen delivery.⁹² ACS is an early event, and its clinical trajectory can be accurately predicted within 3 to 6 hours after ED admission. On admission to the ICU, high-risk patients have significant intra-abdominal hypertension and are in persistent shock. Contrary to conventional wisdom, they do not respond well to preload-directed resuscitation. In fact, continued aggressive resuscitation precipitates the full-blown syndrome [see Figure 14].

As we studied its epidemiology, it became apparent that ACS starts in the ED in patients arriving with severe bleeding who require a massive transfusion. Fundamental changes are needed in pre-ICU care of these patients. Failure to recognize the severe shock, ongoing bleeding, an indiscriminate crystalloid infusion, and failure to prioritize definitive measures for hemorrhage control have been identified as key issues in the ED. In our experience, early overzealous crystalloid resuscitation in the setting of severe bleeding sets the stage for ACS, which we demonstrated to be a modifiable link in the cascade to MOF. Additionally, albumin was the principal colloid used in the early PRCTs, but other types of colloids (starches and gelatins) are now available.

Because of their higher molecular weights, these colloids are confined to the intravascular space, and their infusion results in more rapid and sustained plasma volume expansion. In severe hemorrhagic shock, however, the permeability of capillary membranes increases, allowing colloids to enter the interstitial space, which can then worsen edema and impair tissue oxygenation. The theory that these high-molecular-weight agents plug capillary leaks that occur during neutrophil-mediated organ injury, although enticing, has not been established. Furthermore, Lucas proposed that resuscitation with albumin induces renal failure and even impairs pulmonary function.⁹⁷ Similarly, hetastarch has been shown to induce renal dysfunction in patients with septic shock and in recipients of kidneys from brain-dead donors. Hetastarch (Hespan) also has a limited role in massive resuscitation because it causes a coagulopathy and hyperchloremic acidosis attributable to its high chloride content. Newer hydroxyethyl starch preparations (Hextend, pentastarch) purportedly do not cause these adverse effects but have not been studied in massive resuscitation.⁹⁸

Although we share the belief that colloids might reduce the incidence of ACS, this possible benefit must be weighed

Figure 14 Depicted is the so-called saltwater vicious cycle, which results in the development of abdominal compartment syndrome. The term “filtration secretion” refers to the process by which increasing gut edema causes interstitial pressure to rise to high levels, leading to disruption of the interstitial matrix. Ultimately, as a result, the villus tips spring leaks, through which interstitial fluid passes into the gut lumen. IAP = intra-abdominal pressure.

against the potentially detrimental effects of colloids already reported. ACS occurs in a small subgroup of patients (< 1%) who arrive with severe bleeding and require a massive transfusion.¹⁴ Early prediction models can identify these high-risk patients and an alternative resuscitation strategy that limits isotonic crystalloids and uses massive transfusion protocols that emphasize that early FFP will be beneficial in this subgroup of patients. Finally, alternative crystalloid solutions are being developed that not only expand the intravascular space and replete the extracellular fluid but also have anti-inflammatory properties (e.g., Ringer ethyl pyruvate).⁷⁸ Given

the current evidence that excess fluid resuscitation is harmful, there has been interest in the early use of vasopressors after trauma.⁹⁹ However, a recent multi-institutional epidemiology study showed that patients who had early vasopressors within 12 hours of injury had an 80% increased risk of dying.¹⁰⁰

2 INJURIES TO THE CENTRAL NERVOUS SYSTEM

Kiarash Shahlaie, MD, PhD, Marike Zwienenberg-Lee, MD, Kee D. Kim, MD, and J. Paul Muizelaar, MD, PhD

Traumatic brain injury (TBI) is a leading cause of death and disability in the world. In the United States, over 1.5 million people suffer TBI each year, resulting in over 50,000 deaths and 80,000 permanent disabilities.¹ As a result, over 5.3 million people in the United States currently live with TBI-related deficits, making this an epidemic that dramatically affects patients, their families, and society at large. Although neurosurgeons and neurointensivists are best trained to manage patients with TBI,^{2,3} resuscitation and stabilization of patients in the early period after head injury are typically performed by paramedics, emergency department physicians, general surgeons, and trauma surgeons. These professionals are at the forefront of care for patients with TBI and have the potential to dramatically affect patient outcome.

In the first few hours after head injury, rapid diagnostic evaluation and appropriate neurosurgical consultation are of the utmost importance for patients with TBI. In the hours, days, and weeks following injury, maximal neurologic recovery is achieved by aggressively maintaining adequate cerebral blood flow (CBF) and oxygenation to prevent secondary insults to the injured brain. To optimize outcome in patients with TBI, particularly in the context of significant multisystem injuries, a collaborative, multidisciplinary, evidence-based, protocol-directed approach to patient care should be used by modern-day trauma centers.

According to the National Spinal Cord Injury Statistical Center, approximately 12,000 people present to a hospital in the United States each year with a new spinal cord injury (SCI). As of 2008, it is estimated that between 229,000 and 306,000 in the United States live with SCI-related deficits. Most injuries result from motor vehicle accidents (42.1%); 15 to 20% are attributable to falls, 15 to 20% result from interpersonal violence, and the remaining 15 to 20% are associated with sports and recreational activities. Over the past two decades, the proportion of injuries associated with sports has decreased, whereas the proportion attributable to falls has increased. The average age at SCI continues to steadily rise; since 2005, the average age of patients suffering SCI is 40.2 years (between 1973 and 1979, it was 28.7 years). Although there continues to be a slight trend toward an increasing percentage of females, the vast majority of patients suffering SCI are males (80.9%). Between 45 and 50% of patients with SCI have other injuries that seriously affect their prognosis.

The cervical spine is most often involved in SCI (55%), followed by the thoracic (30%) and lumbar levels (15%). In an analysis of 358 patients with SCI, complete neurologic injury occurred in 78% of the 71 cases of thoracic injury, 65% of the 85 cases of thoracolumbar injury, and 60% of the 202 cases of

cervical injury.⁴ Average direct costs of SCI (including hospitalization, rehabilitation, residence modification, and long-term care) are tremendous. According to the National Spinal Cord Injury Statistical Center, the lifetime costs of a 25-year-old suffering low (C5 to C8) or high (C1 to C4) quadriplegia is \$3,160,137 or \$1,786,836, respectively; the average yearly expense of a patient with high quadriplegia is \$801,161 in the first year and \$143,507 each subsequent year.

Initial resuscitation and evaluation of injured patients are discussed more fully elsewhere. In this chapter, we outline approaches to the management of severe head injury and acute SCI. In addition, we address the pathophysiology of such injuries to provide the reader with the understanding required for making appropriate decisions about diagnosis and treatment of injured patients [see Discussion, *below*].

Head Injury

EMERGENCY DEPARTMENT MANAGEMENT

Hypoxia and hypotension are two of the worst secondary insults following TBI and should be avoided at all costs during initial patient management. Severe oxygen desaturation (< 60%) during transport to the hospital is associated with a 3.5-fold increase in mortality,⁵ and duration of in-hospital oxygen desaturation (< 90%) is an independent predictor of mortality.⁶ One episode of post-TBI hypotension doubles mortality risk, whereas two or more episodes increase the relative risk of mortality to 8.1,⁷ and the total duration of hypotensive episodes is a significant predictor of morbidity and mortality.⁶ Patients with SCI above T5 are particularly prone to severe hypotension as a result of vasogenic spinal shock and should be aggressively treated with volume resuscitation and administration of alpha-adrenergic vasopressors. Therefore, aggressive and complete physiologic resuscitation is the highest priority for patients with head and spinal cord injuries.

A multidisciplinary team should provide an adequate airway, deliver sufficient oxygenation and ventilation (intubation, ventilation, and detection of hemothorax or pneumothorax), and establish hemodynamic stability (with adequate fluid replacement and detection and treatment of any bleeding), all according to the principles developed by the advanced trauma life support system. The ABCs of emergency care (airway, breathing, and circulation) always take precedence, and patients' neurologic injuries should not distract caretakers from these important principles of trauma management. The initial neurologic assessment, which should take no more than a few seconds, consists of rating the patient's level of consciousness on the Glasgow Coma Scale (GCS) [see Table 1] and assessing the

Table 1 Glasgow Coma Scale

Test	Response	Score
Eye opening (E)	Spontaneous	4
	To verbal command	3
	To pain	2
	None	1
Best motor response (arm) (M)	Following verbal command	6
	Localization to pain	5

*3T–11T when intubated.

diameter and reactivity of the pupils. Although the same assessment is made after resuscitation as a guide for prognosis and therapy, it should also be made (and recorded) before resuscitation to permit evaluation of the effect of resuscitative measures and differentiation between primary and secondary neurologic injury.

Early orotracheal intubation and ventilation are recommended for patients with a GCS score of 8 or lower or a motor score of 4 or lower. Other indications for immediate intubation are loss of protective laryngeal reflexes and ventilatory insufficiency, as manifested by hypoxemia (arterial oxygen tension $[P_{aO_2}] < 60$ mm Hg), hypercarbia (arterial carbon dioxide tension $[P_{aCO_2}] > 45$ mm Hg), spontaneous hyperventilation (causing $P_{aCO_2} < 26$ mm Hg), and respiratory arrhythmia. Indications for intubation before transport are deteriorating consciousness (even if the patient is not in a coma), bilateral fractured mandible, copious bleeding into the mouth (as occurs with fracture of the base of the skull), and seizures. Patients with TBI should be normoventilated ($P_{aCO_2} \approx 40$ mm Hg) unless they clearly demonstrate signs of raised intracranial pressure (ICP) (see below).

Fluid replacement should be performed with isotonic solutions such as normal saline or packed red blood cells when appropriate. Although appropriate in certain clinical scenarios, lactated Ringer (LR) solution should generally be avoided in patients with TBI as it has been shown to increase ICP⁸ and decrease intracranial compliance.⁹ Hypertonic saline (HS) may be more appropriate in patients with TBI as it has been shown to improve intracranial compliance and lower ICP, and in a randomized prospective trial of pediatric TBI, HS was shown to result in lower ICP, higher cerebral perfusion pressure (CPP), higher serum sodium, and fewer complications and shorter intensive care unit (ICU) stays when compared with patients receiving LR solution.¹⁰

Glucose-based solutions should be avoided in adult patients with TBI. Elevated serum glucose in the first 24 hours

after TBI or following surgical intervention is associated with worse neurologic outcome.^{11,12} In a recent review from the IMPACT study, hyperglycemia on admission or during hospital course is an independent prognostic indicator of outcome 6 months following TBI.^{11,13} A recent review of 77 patients with severe TBI identified early hyperglycemia as a strong predictor of poor outcome and death.¹⁴

Intracranial hypertension should be treated aggressively as it is a primary predictor of outcome in the acute period following TBI. Hyperventilation reduces ICP by decreasing cerebral blood volume (CBV) and does not interfere with volume resuscitation. Because it can result in iatrogenic cerebral ischemia, however, it should be used only in patients with acute neurologic deterioration with lateralizing signs (e.g., anisocoria, unilateral motor posturing). Hyperosmolar therapies are also effective agents for reduction of ICP but have differing effects on volume status. Mannitol is an osmotic diuretic that has long been used in the setting of TBI and is thought to reduce ICP by drawing free water out of the brain as well as improving blood rheology, resulting in improved CBF and reduced CBV.¹⁵ It has been shown that pupillary abnormalities following TBI not only result from oculomotor nerve compression but also reflect brainstem ischemia attributable to compression. Therefore, administration of mannitol is effective because it not only decreases ICP but also increases CBF through modulation of viscosity. Given that mannitol results in diuresis and dehydration, its use in hypotensive patients may not be prudent and should be preventively followed with intravenous fluid boluses. HS may be a preferable hyperosmolar agent in this setting as it promotes fluid resuscitation while providing all of the ICP-lowering benefits of mannitol.^{16,17} It is important to note that arterial hypertension following severe head injury may reflect intracranial hypertension (Cushing phenomenon), especially when accompanied by bradycardia; it should not be directly treated, because it may be the sole mechanism permitting the brain to maintain perfusion despite increasing ICP.

In the absence of signs of herniation, sedation should be used when required for safe and efficient transport of the patient. Transport time should be kept to a minimum because transport is often accompanied by secondary insults (e.g., hypoxia or hypotension). Pharmacologic paralysis, which interferes with neurologic examination, should be used only if sedation alone is inadequate for safe and effective transport and resuscitation. When pharmacologic paralysis is used, short-acting agents are preferred. As noted above, prophylactic hyperventilation may exacerbate early ischemia and should not be used in patients with suspected TBI. Guidelines for the resuscitation and initial treatment of patients with severe head injuries have been established that facilitate management [see Figure 1].

After hemodynamic stability is achieved, unenhanced computed tomography (CT) of the head should be performed in all patients with persistent impairment of consciousness. In most institutions, a CT scan of the cervical spine is also obtained for evaluation of cervical spine injury in patients with severe head injury. Various criteria have been described to determine the necessity of head CT scan in patients with suspected TBI, including the Canadian Head CT Rule and the New Orleans Criteria. A summary of these guidelines is presented in Table 2.

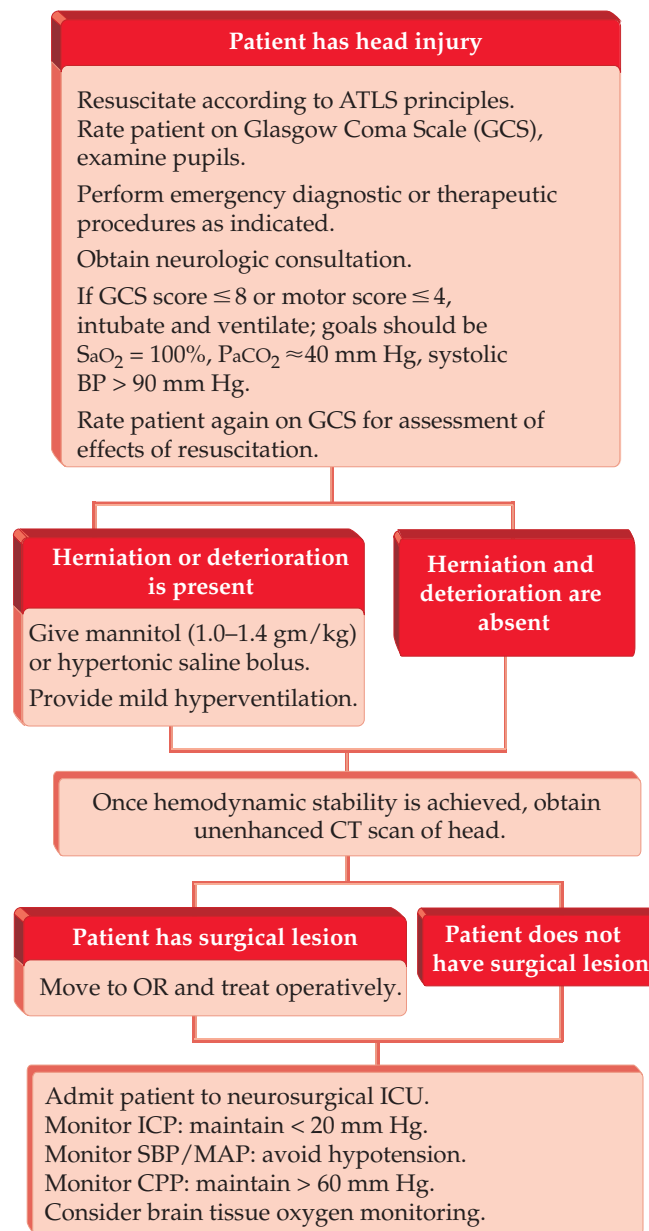

Figure 1 ATLS = advanced trauma life support; BP = blood pressure; CPP = cerebral perfusion pressure; CT = computed tomography; ICP = intracranial pressure; ICU = intensive care unit; OR = operating room; PaCO₂ = arterial carbon dioxide tension.

OPERATIVE MANAGEMENT

Guidelines for the surgical management of severe TBI were recently published in a supplement to the journal *Neurosurgery*.¹⁸ In general, extra-axial hematomas (e.g., subdural and epidural) that result in at least 5 mm of midline shift are candidates for surgical evacuation and should be immediately evaluated by neurosurgical consultants. Evacuation of epidural or subdural hematomas can dramatically reduce ICP, improve CPP, and optimize CBF so as to prevent secondary insults to the injured brain. Evacuation of subdural

Table 2 Indicators Necessitating Non-contrast Head CT Scan in Patients with Loss of Consciousness and GCS Score of 14 or 15

Sign and symptoms Headache Somnolence Mental status changes or confusion Nausea or vomiting Seizure	Perseveration Neurologic deficit Blurred or double vision Vertigo Hemotympanum, raccoon eyes, CSF leak, Battle sign
Clinical history Dangerous mechanism Drug or alcohol intoxication	Age over 60 years

CSF = cerebrospinal fluid; CT = computed tomography; GCS = Glasgow Coma Scale.

hematomas has been shown to dramatically decrease elevated ICP¹⁹ and reverse cerebral ischemia,²⁰ and surgical evacuation of subdural hematomas within 4 hours of injury has been shown to improve clinical outcome.²¹ With widespread accessibility of emergent CT scans, routine exploratory burr holes are no longer appropriate in the management of TBI. In cases of progressive neurologic deterioration with suspected intracranial hematoma, therefore, moderate hyperventilation (PaCO₂ ≈ 30 mm Hg) and high-dose mannitol (1.0 to 1.4 g/kg) should be administered while the patient receives a CT scan and is prepared for surgical evacuation.

Posterior fossa hematomas, which are rare, also require urgent evacuation because obstructive hydrocephalus and brainstem compression can result in rapid neurologic deterioration. Current guidelines recommend surgical evacuation of posterior fossa hematomas with associated neurologic dysfunction or those that result in mass effect on CT scan, including “distortion, dislocation, or obliteration of the fourth ventricle.”¹⁸

ICU MANAGEMENT

Once patients are adequately resuscitated, evaluated, and treated for urgent indications (e.g., hematoma evacuation), they should be rapidly transferred to an ICU for neurocritical care management. Efforts should be made to manage patients with severe TBI in neuroscience ICUs as studies have shown that outcome from TBI is significantly improved when patients are managed in a specialized unit with direct involvement of neurosurgery and/or neurocritical care services.²

The focus of ICU management is the prevention of secondary insults to the injured brain. To ensure optimal cerebral oxygenation, efforts should be made to control cerebral metabolic demand (prevent fevers and seizures, induce sedation or coma) and support CBF and oxygenation (optimize hemoglobin concentration, oxygen saturations, and CPP; maximize cerebral vessel diameter; limit blood viscosity). Despite these efforts, admission to an ICU does not eliminate the occurrence of secondary insults. In a series of 124 patients admitted to a neurosurgical ICU, more than one episode of hypotension occurred in 73% of all patients, and more than one episode of hypoxia occurred in 40%.⁶ In another study, online monitoring of CPP, jugular venous

oxygen saturation (S_{rO_2}), local CBF, and brain tissue oxygenation was performed in 14 patients who had sustained a severe head injury; 37% of the episodes involving decreased CBF, CPP, and saturation were related to clinical and nursing procedures.²² Nonetheless, limiting the occurrence and duration of secondary insults significantly improves neurologic outcome in patients with severe TBI.

Monitoring

A variety of bedside devices are currently available for monitoring ICP, local CBF, and local and global cerebral oxygenation.

ICP monitoring ICP monitoring is indicated in all salvageable patients with a GCS score less than or equal to 8 (after resuscitation) with an abnormal head CT scan. In patients with a normal head CT scan but a low GCS, ICP monitoring is indicated if two of the following are present: age above 40 years, motor posturing, or hypotension (< 90 mm Hg).²³ It is important to note that a “negative” head CT scan does not reliably predict ICP. In patients with two of the three above characteristics and a negative head CT scan, 53 to 63% had ICP above 20 mm Hg. Narayan and colleagues reported a 13% incidence of elevated ICP in patients with a “normal CT scan on admission,”²⁴ and Eisenberg and colleagues found that severe TBI patients with an initial negative head CT had a “10-15% chance of developing elevated pressure.”²⁵ As a result, currently published guidelines recommend protocol-directed placement of ICP monitors rather than subjective placement based on CT scan results alone.

Current guidelines continue to recommend aggressively maintaining ICP below 20 mm Hg in patients with severe TBI. ICP above 20 mm Hg is a significant independent determinant of outcome, and a recent study of 233 patients found ICP greater than 15 mm Hg to be one of five independent risk factors for death.²⁶ Patients whose ICP is maintained below 20 mm Hg have significantly better outcome, and a recent systematic review found that ICP 20 to 40 mm Hg increased mortality by 3.5-fold and ICP above 40 mm Hg increased mortality by 6.9-fold; raised but reducible ICP increases mortality by 3- to 4-fold, and refractory ICP was associated with an odds ratio for death of 114.3.²⁷ Although monitoring of ICP has never been subjected to a prospective, randomized clinical trial, it continues to play a fundamental role in neurocritical care management of patients with severe head injury. Implementation of an ICP-based protocol for TBI patients has been shown to significantly improve outcome,²⁸ and patients whose ICP responds to pharmacologic therapy have a better outcome.

Brain tissue oxygen monitoring Direct measurement of local brain tissue oxygen tension (P_{btO_2}) has become increasingly popular in the management of severe TBI and has been adopted as an adjunct or replacement to jugular bulb oximetry by many neurotrauma centers (see below). Used in Europe for many years before its approval by the US Food and Drug Administration in 2001, these probes are typically inserted into radiographically uninjured subcortical white matter and used as indicators of global cerebral oxygenation.²⁹ These probes measure oxygen tension in brain tissue and are most sensitive to changes in

system arterial oxygenation (P_{aO_2}) and CBF.³⁰ Normal values range between 25 and 30 mm Hg.

One impetus behind P_{btO_2} monitoring is the observation that brain oxygen does not always correlate with CPP and is often reduced after successful resuscitation of TBI patients, even when hemodynamically stable. ICP and CPP monitoring, which has long been used to ensure adequate CBF, may not be sufficient for providing adequate cerebral oxygenation. In fact, Stiefel and colleagues at the University of Pennsylvania found that 29% of patients with ICP less than 25 mm Hg and 27% of patients with CPP greater than 60 mm Hg experience severe cerebral hypoxia ($P_{\text{btO}_2} < 10$ mm Hg), and 47% of patients who seem to be “optimally managed” (ICP < 25 mm Hg and CPP > 60 mm Hg) experience P_{btO_2} less than 20 mm Hg and 21% P_{btO_2} less than 10.143 mm Hg.³¹ P_{btO_2} closely and linearly correlates with regional CBF; levels below ischemia (18 mL/100 g/min) correlate with P_{btO_2} of 22 mm Hg.

Another reason for P_{btO_2} monitoring is the observation that neurologic outcome is significantly worse in patients with reduced P_{btO_2} .³¹ P_{btO_2} values less than 8 to 10 mm Hg represent a high risk of ischemia and increased mortality, and any episode of P_{btO_2} less than 7 mm Hg is associated with risk of death regardless of duration.³² In a study of 60 patients, P_{btO_2} strongly correlated with good outcome ($P_{\text{btO}_2} > 35$ mm Hg), moderate or severe disability (P_{btO_2} 26 to 35 mm Hg), and a vegetative state or death ($P_{\text{btO}_2} < 26$ mm Hg).³³ P_{btO_2} is a very strong predictor of outcome (diagnostic sensitivity 92%, specificity 84%) and directly correlates with GCS on admission, CPP, and brain glucose levels; P_{btO_2} below 19 mm Hg was invariably associated with a vegetative state or death in this study.³⁴ A prospective study of 101 patients found a worse outcome if P_{btO_2} was below 10 mm Hg for over 30 minutes; a 50% risk of death was found in patients with P_{btO_2} below 15 mm Hg for 4 hours.³⁵

Although a clinical trial of ICP/ CPP- versus ICP/ CPP/ P_{btO_2} -directed therapy has not been completed (one is currently under way), there is evidence that efforts to increase P_{btO_2} may result in improved neurologic outcome. In a report by Stiefel and colleagues, adopting an oxygen-directed severe TBI protocol to maintain P_{btO_2} greater than 25 mm Hg coincided with a significant decrease in mortality from severe TBI at their institution (25% versus 44%), prompting the design of a prospective, randomized clinical trial.³¹

One potential mechanism of decreased P_{btO_2} despite normal ICP and CPP is posttraumatic vasospasm (PTV), a significant source of secondary insult that occurs in 19 to 50% of patients with severe TBI.³⁶⁻³⁸ PTV typically develops between 12 hours and 5 days after injury, lasts anywhere between 12 hours and 30 days, and is an independent predictor of permanent neurologic deficit and poor outcome in many studies. Recently, the use of brain tissue oxygen probes to detect and direct therapy for PTV was described,³⁹ further supporting the role of brain tissue oxygen monitoring in the management of severe TBI.

Current TBI guidelines do not address indications for brain tissue oxygen monitoring in severe TBI but do recommend that P_{btO_2} be maintained above 15 mm Hg at all times.⁴⁰ The treatment algorithm used at our institution to maintain P_{btO_2} levels above this threshold is presented in Figure 2.

Figure 2 P_{bt}O₂ = brain tissue oxygen; ABG = arterial blood gas; CBF = cerebral blood flow; CPP = cerebral perfusion pressure; CSF = cerebrospinal fluid; CT = computed tomography; EEG = electroencephalogram; F_iO₂ = fraction of inspired oxygen; HOB = head of bed; HS = hypertonic saline; ICP = intracranial pressure; MAP = mean arterial pressure; P_aO₂ = arterial oxygen tension; P_{CO₂} = carbon dioxide tension; PEEP = positive end-expiratory pressure; PRBC = packed red blood cell; TCD = transcranial Doppler.

Jugular bulb oximetry Simultaneous monitoring of arterial (S_aO₂) and S_{jv}O₂ can be used to estimate the arterial-jugular venous oxygen difference (AVDO₂), an important

indicator of the adequacy of CBF. S_{jv}O₂ is monitored by percutaneous retrograde insertion of a fiberoptic catheter in the internal jugular vein, with the tip of the catheter located in the jugular bulb. The catheter is usually inserted into the jugular vein with the dominant cerebral venous drainage (the right jugular vein in 80 to 90% of the population), but some prefer to insert the catheter ipsilateral to the most brain damage. AVDO₂ is calculated according to the following formula:

$$AVDO_2 = (S_{aO_2} - S_{jvO_2}) \times 1.34 \times Hb + [(P_{aO_2} - P_{jvO_2}) \times 0.0031]$$

The contribution of the variables within the brackets, which is small, is usually ignored for practical purposes. Because calculation of AVDO₂ requires the drawing of blood samples, it can be done only intermittently.

Continuous monitoring of S_{jv}O₂ can be performed, with normal values ranging between 50 and 70%. Episodes of S_{jv}O₂ less than 50% for > 15 minutes correspond with desaturations, which may result from insufficient arterial oxygenation (S_aO₂), inadequate oxygen-carrying capacity (Hb concentration), or inadequate CBF. These episodes of desaturation are strongly associated with neurologic outcome and mortality.

The limitations of jugular bulb oximetry should be kept in mind when S_{jv}O₂ values are interpreted.^{41,42} Because S_{jv}O₂ represents global oxygenation, regional ischemia may go undetected if the ischemic region is too small to be represented in the total hemispheric S_{jv}O₂ value. Ischemia may also occur in a part of the brain being drained by the opposite jugular vein. In addition, extracerebral veins drain into the internal jugular vein approximately 2 cm below the jugular bulb. With low flow values, significant extracerebral contamination may occur, resulting in deceptively high S_{jv}O₂ values. Finally, artifactual readings are often encountered as a result of reduced light intensity when the catheter lodges against the vessel wall. Technical improvements in catheters, however, have markedly reduced the number of artifacts observed.

Management of CPP

CPP is calculated from mean arterial pressure (MAP) and ICP (CPP = MAP – ICP), and is used as an indicator of CBF. Maintaining adequate CPP following TBI has been shown to improve outcome in many studies, although the “ideal” CPP level seems to vary among and within patients over time. Early studies seemed to suggest that neurologic outcome directly correlated with elevated CPP, with several studies suggesting that CPP 70 to 80 mm Hg was the clinical threshold below which mortality and morbidity increase.^{43–45} A retrospective analysis of 392 patients with TBI found that MAP below 70 mm Hg and/or CPP below 60 mm Hg were independent predictors of poor outcome.⁴⁶ Cerebral microdialysis studies shed further light on this topic, suggesting that ischemic insults to the brain occurred when CPP dropped below 50 mm Hg.⁴⁷ These studies suggested that maintaining an elevated CPP was an effective strategy for optimizing outcome following severe TBI.

However, a randomized clinical trial of “CPP-targeted therapy” (CPP > 70) versus “ICP-targeted therapy” (CPP > 50, ICP < 20) highlighted the importance of considering other organ systems when managing severe TBI patients. In this study, Contant and colleagues found no significant

difference in neurologic outcome between the two strategies but reported a higher morbidity in patients receiving CPP-targeted therapy because of a fivefold increased risk of acute lung injury (ALI).⁴⁸ At the same time, a separate large, international trial reported that maintaining CPP greater than 60 mm Hg was not beneficial.⁴⁹

As a result, current published guidelines recommend against aggressively maintaining CPP above 70 mm Hg (because of the risk of ALI) but also recommend aggressive measures to keep CPP above 50 mm Hg at all times.⁵⁰ As a result, most centers have adopted a CPP goal of 60 mm Hg, although this can be adjusted by the neurosurgical or neurocritical care service based on the patient's pressure autoregulation status. Management strategies for CPP therapy include reduction of ICP and support of MAP. MAP support is first accomplished with optimization of fluid status to central venous pressures (CVPs) of 8 to 10 mm Hg (pulmonary arterial wedge pressure 12 to 14 mm Hg). If this is insufficient to maintain an adequate CPP, an alpha-adrenergic infusion should be used. Phenylephrine is an optimal agent for management of CPP following severe TBI as it has minimal vasopressive effects on cerebral vasculature.

Management of ICP

Elevated ICP can significantly compromise CPP and promote herniation syndromes, and current guidelines recommend initiation of therapies when measurements reach 20 mm Hg.⁵¹ As mentioned above, ICP values above 20 mm Hg independently determine outcome, and patients whose ICP is maintained below 20 mm Hg during their hospital stay have significantly better neurologic recovery.²⁵ Therefore, it is important to institute preventive measures in all patients with severe TBI, and therapeutic measures for ICP elevations above 20 mm Hg should be instituted in a timely and aggressive manner. Prophylactic measures to prevent elevation of ICP include patient positioning, temperature management, seizure prophylaxis, electrolyte balance, and choice of intravenous maintenance fluids. Therapeutic measures include cerebrospinal fluid (CSF) drainage, sedation, chemical paralysis, hyperosmolar therapy, hypothermia, hyperventilation, decompressive surgery, metabolic coma.

Prophylactic measures *Patient positioning* Patient positioning can have a dramatic effect on ICP and should be optimized for each patient. A neutral head position allows for maximal venous outflow through the jugular veins, and any deviation from neutral (neck flexion, extension, lateral deviation, rotation) can result in elevation of ICP. Placement of a cervical collar can also cause a significant increase in ICP; in one series, the mean rise in ICP attributed to collar placement was approximately 4.5 mm Hg.⁵² A study in patients undergoing lumbar puncture found a significant increase in CSF pressure from 17.7 to 24.8 cm H₂O with placement of a rigid Philadelphia collar.⁵³

Elevation of the head of the bed from 0 to 30° significantly decreases ICP without changing CPP, CBF, cerebral metabolic rate of oxygen (CMRO₂), arteriovenous difference of lactate (AVD_{lactate}), cerebrovascular resistance (CVR), or brain tissue oxygenation.⁵⁴ Ninety-three percent of the ICP-lowering effects of head elevation are achieved at 30°;⁵⁵ and head elevation above 45° can result in reduced CPP with a resultant increase in ICP. It is recommended, therefore, that

elevation of the head of the bed should be maintained at 30 to 45° for patients with severe TBI.

Temperature management Hyperthermia following TBI can increase ICP and reduce CPP and is associated with worsened outcome. Hypothermia produces a balanced reduction in energy production and use, decreasing CMRO₂ and CBF proportionally. In a study of 846 patients with severe TBI, pyrexia was one of six factors strongly associated with outcome at 1 year,⁵⁶ and studies have shown that fevers are particularly common in patients with head injury. An analysis of 4,259 patients managed in a neurology/neurosurgery ICU found that elevated body temperature is an independent predictor of ICU stay, hospital stay, functional outcome, and mortality following TBI.⁵⁷

Prophylactic mild hypothermia has been advocated by some authors,⁵⁸ and prophylactic moderate hypothermia has been studied in randomized clinical trials with inconclusive results (studies are still ongoing with more select patient subgroups).^{59,60} The main side effects of hypothermia are cardiac arrhythmias and coagulation disorders, reported after cooling to 32° to 33°C. Other drawbacks of hypothermia include the difficulty of detecting infection because of the lack of warning signs (e.g., spiking and elevated temperature) and the need for specialized equipment (e.g., rotor beds with cooling control) and personnel to induce and maintain the condition. At present, evidence is insufficient to support prophylactic moderate hypothermia, but aggressive support of euthermia (or mild hypothermia to 35°C) may be appropriate in patients with severe TBI.

Seizure prophylaxis Posttraumatic seizures can cause a dramatic increase in CBF, CBV, and ICP, and prevention may also reduce the risk of chronic epilepsy. In a large randomized, double-blind, placebo-controlled trial by Temkin and colleagues, phenytoin therapy was found to significantly reduce the incidence of early (days 0 to 7) seizures from 14.2 to 3.6% but had no effect on late seizures or long-term survival rates.^{61,62} Patients treated with phenytoin demonstrated impaired neuropsychological test performance 1 month after injury; however, this difference was not present at the 12-month evaluation.⁶³ Of note, Young and colleagues performed a randomized, double-blind trial of 244 TBI patients and found no effect of dilantin on preventing early or late post-traumatic seizures.⁶⁴ However, the incidence of posttraumatic seizures was low in both groups, and it is unclear if therapeutic phenytoin levels were achieved: no patient with serum phenytoin greater than or equal to 12 µg/mL experienced a seizure. In the Temkin and colleagues study, over 70% of patients treated with phenytoin had therapeutic serum levels.⁶² Current guidelines by the Brain Trauma Foundation, the American Academy of Neurology Quality Standards Subcommittee, and the Brain Injury Special Interest Group of the American Academy of Physical Medicine and Rehabilitation recommend the use of phenytoin for 7 days following severe TBI, with efforts made to target therapeutic levels.⁶⁵

Electrolyte and IV fluid management Hyponatremia can promote secondary insults to the injured brain by promoting cerebral edema and lowering seizure threshold. Hyponatremia occurs in 17.4 to 33% of patients suffering severe TBI, and is often attributed to cerebral salt wasting and/or syndrome of inappropriate antidiuretic hormone (SIADH).^{66,67} An IMPACT database review of 5,270 TBI patients

identified hyponatremia on admission as strongly correlating with poor outcome.¹¹ Given that sodium concentration is 77 mg/dL in 0.45% saline and 130 mg/dL in LR solution, normal saline is the intravenous fluid of choice for management of patients with severe TBI. Use of “half-normal” (0.45%) saline has been shown to promote cerebral swelling and increased ICP,⁶⁸ and failure to rapidly correct hyponatremia has been associated with cognitive impairments during the recovery phase, although the threshold of effects varies significantly among individuals. Cerebral salt wasting following TBI is likely attributable to release of brain natriuretic peptide, a potent vasodilator and natriuretic that is elevated in serum during the acute phase of TBI.⁶⁹

Similarly, fluid imbalance (either hyper- or hypovolemia) can also result in increased ICP, albeit by different mechanisms. Hypovolemia can compromise cardiac output and CPP, triggering cerebral vasodilation (in patients with intact autoregulation) that results in increased CBV and elevation in ICP. Hypervolemia may also result in increased ICP, particularly in patients with impaired cerebral autoregulation who are unable to vasoconstrict in response to increased MAP. Therefore, euvolemia is the safest and most prudent treatment strategy for patients with severe TBI.

Therapeutic measures Patients who experience elevated ICP despite the above prophylactic measures should be managed by a protocol-directed, tiered approach [see Figure 3].

Therapies within a tier should be maximized before moving to a higher tier, and careful consideration should be given to repeat head CT scans when a patient requires escalation of therapy (to evaluate for intracranial lesion progression). It is generally not advisable for escalation of tiered therapy to occur without careful assessment by the treating neurosurgeon or neurointensivist as some etiologies of elevated ICP may result from reversible events (e.g., hypoventilation) that require more specific treatment strategies.

Hyperosmolar therapy Mannitol and HS can be delivered in boluses for acute control of ICP, but in adults, it is not typically used as a regular, intermittent therapy. They can be used across all tiers of therapy but are limited by their side effects of induced serum hyperosmolality and induced hyponatremia.

Mannitol is usually administered in intravenous boluses of 0.25 to 1 g/kg over 10 to 15 minutes, until either ICP is controlled or serum osmolality reaches 320 mOsm/L. There is some evidence suggesting that higher doses (e.g., 1.4 g/kg) may be more effective,^{70,71} although the integrity of these studies has been questioned. Because volume depletion is an important side effect of mannitol therapy, urine losses should be replaced. HS (3 to 10%) may be used in place of mannitol: it appears to be equal or superior to mannitol for ICP control and can be delivered in varying concentrations (e.g., 3%, 7.5%, 23.4%).⁷² In addition, HS is not associated with volume depletion but actually increases intravascular volume, which

Figure 3 ICP = intracranial pressure; CPP = cerebral perfusion pressure; CSF = cerebrospinal fluid; CT = computed tomography.

may be preferable during resuscitation or in patients with decreased CVP. As mentioned above, the therapeutic effects of hyperosmolar therapies likely involve both osmotic and rheologic mechanisms.

TIER I CSF drainage has no known deleterious side effects but does have the potential risk of aggravating brain shift (depending on the side of its insertion relative to the side of injury). In general, it is best to drain the minimal amount of CSF necessary to maintain ICP below 20 mm Hg.

Various sedation strategies have been described for patients with severe TBI, all of which aim to reduced cerebral metabolic demand and, in turn, CBV and ICP. Most strategies include analgesic and anxiolytic drug infusions. Bolus delivery of these medications should be avoided in patients with severe TBI as this can result in induced hypotension, reduction of MAP and CPP, and reflexive cerebral vasodilation that causes elevation in ICP and further compromise of CPP and CBF. Agents with short half-lives and few active metabolites are preferable as they permit intermittent interruption of sedation to assess neurologic function, a strategy that has been shown to reduce ICU stay, ventilator dependence, and the need for repeat imaging and diagnostics.^{73,74} It is important to note, however, that these interruptions in sedation should not be performed in patients with elevated ICP and poor intracranial compliance as the risks of ICP spikes far outweigh the benefits of intermittent neurologic examination.

Many neuroscience ICUs prefer the use of fentanyl and propofol for ICP control as they are relatively shorter-acting agents that have demonstrated success in management of severe TBI. Propofol is a sedative hypnotic with a rapid onset and a short duration of action.^{75,76} In patients requiring more than 48 hours of sedation, propofol infusion results in significantly fewer ventilator days than treatment with intermittent lorazepam⁷⁷ and has a more favorable economic profile and shorter weaning time than midazolam.⁷⁸ In moderate and severe TBI patients, a prospective trial found significantly improved ICP control with propofol infusion (versus morphine).⁷⁹ In a recent multicenter, retrospective study, a propofol-based protocol resulted in lower ICP, higher CPP, and significantly improved survival (81.8% versus 46.7%).⁸⁰ Because propofol can have deleterious side effects after prolonged use (i.e., > 48 to 72 hours), adults should be closely monitored for “infusion syndrome” and children requiring prolonged sedation should be managed with midazolom infusion. Propofol is delivered via a preservative-free, lipid-base vehicle, which carries a high caloric content (1 kcal/mL) and should be accounted for when determining caloric balance.

As sedation is maximized for ICP control, patients may experience relative hypotension with CPPs dropping below 60 mm Hg. Intravenous volume expansion should be used to target CVPs of 8 to 10 mm Hg, after which a phenylephrine infusion should be instituted and titrated to CPP (and not MAP) goals.

TIER II After maximizing sedation and supporting CPP, many clinicians will institute muscular paralysis for ICP control. Although its efficacy may vary among patients, pharmacologic paralysis can be used in conjunction with maximal sedation to further reduce ICP. Paralysis is also achieved using continuous intravenous infusion and should be titrated

to effect (using percutaneous peripheral nerve stimulation). Although muscular paralysis compromises most of the neurologic examination, it is important to remember that neuromuscular blockade does not interfere with pupillary response, which is mediated by smooth muscle contraction.

Hyperventilation can be used as a strategy for ICP lowering despite maximal sedation and chemical paralysis but carries the risk of iatrogenic cerebral ischemia.⁸¹ Therefore, mild to moderate hyperventilation should *only be used in patients with a continuous brain oxygenation monitor*, such as a brain tissue oxygen probe or jugular bulb oximetry monitor.

TIER III Decompressive craniectomy is an important component of protocol-driven therapy for patients with severe TBI and should be performed in patients who have exhausted TIER I and II therapies and do not have adequate ICP control with intermittent hyperosmolar therapies. The effects of decompressive craniectomy on ICP are often dramatic: Olivecrona and colleagues performed decompressive craniectomy in 21 patients with elevated ICP despite evacuation of hematomas, sedation, CSF drainage, and pentothal infusion and found that mean ICP decreased from 36.4 to 12.6 mm Hg; they reported a trend toward improved outcome in these patients.⁸² Aarabi and colleagues found that 85% of patients have ICP below 20 mm Hg following decompressive craniectomy (mean ICP 23.9 mm Hg versus 14.4 mm Hg), and outcome at 3 months was significantly better than expected in patients who underwent craniectomy.⁸³ Timofeev and colleagues reported 49 patients who underwent craniectomy for refractory ICP; at the 6-month follow-up, 61.2% had a favorable outcome, 20.5% remained severely disabled, and 18.4% were left in a vegetative state.⁸⁴

Historically, decompressive craniectomy has been thought of as a TIER IV therapy, but there is significant evidence advocating its earlier use in protocol-directed TBI management. Albanese and colleagues studied very severe TBI patients with a high risk of brain death and performed decompressive craniectomy either before or after placement of an ICP monitor (based on injury severity, patients with absent pupillary responses underwent immediate craniectomy).⁷² Overall, they found that 25% of patients attained social rehabilitation at the 1-year follow-up. The size of craniectomy is also an important consideration when performing these procedures. A large multicenter study in China compared the effects of a standard trauma craniectomy (frontotemporoparietal, 12 × 15 cm, $n = 241$) to a limited craniectomy (temporoparietal, 6 × 8 cm, $n = 245$) for refractory ICP and found significantly increased “good outcome” at 6 months (39.8% versus 28.6%) with more extensive bone removal.⁸⁵ Currently, a prospective, randomized, multicenter, international trial (RESCUEicp study) is under way to more definitively establish the role of early decompressive craniectomy in TBI.⁸⁶

TIER IV Moderate hypothermia and barbiturate metabolic coma are highly effective means of reducing ICP but are associated with significant morbidity. As a result, many centers are considering surgical intervention prior to inducing barbiturate coma. Decompressive craniectomy, with or without lobectomy, can carry increased morbidity and mortality in patients who are receiving barbiturate infusion as they are often dependent on pressors to maintain adequate CPP and are less able to tolerate significant blood loss. It is important

to note, however, that many experts still advocate maximizing medical therapies (including barbiturate coma) prior to surgical intervention. In the absence of more definitive data on early decompressive craniectomy, it is important to have neurosurgical consultants intimately involved in patient care as TIER III and IV therapies are being considered.

High-dose barbiturate infusion for TBI was first described in the 1930s and is the most effective medical therapy for ICP control. In patients whose ICP does not respond to conventional therapy, barbiturate treatment is two to four times more likely to control ICP, and the likelihood of survival in patients who respond to barbiturates is 92% at 1 month (versus 17% for nonresponders).²⁵ Barbiturates appear to protect the brain and lower ICP through several mechanisms, including alteration of vascular tone, suppression of metabolism, and inhibition of free radical lipid peroxidation. The most important effect may involve coupling of CBF to regional metabolic demands, so the lower the metabolic requirements are, the lower the CBF and the related CBV, with subsequent beneficial effects on ICP and global cerebral perfusion. Barbiturate therapy (usually pentobarbital to a blood level of 4 mg/L) is instituted when other measures to control ICP fail. In one series of 25 patients with an ICP higher than 40 mm Hg, barbiturates not only controlled ICP but also improved outcome.⁸⁷ In a separate study, however, 54% of patients placed on barbiturate therapy experienced hypotension (compared with 7% of control subjects),⁸⁸ and others have attributed barbiturate therapy with worse neurologic outcome.^{88,89} Barbiturates are a powerful tool for control of ICP, but their use should be carefully scrutinized and monitored.

Hemoglobin, hematocrit, and blood viscosity Hematocrit and viscosity are inversely related, and a balance must be established to optimize oxygenation. If the hematocrit is too high, viscosity increases; if the hematocrit is too low, the oxygen-carrying capacity of blood decreases. Historically, neurosurgeons and neurointensivists have felt that the ideal balance between these factors is a hematocrit around 30%; below this, oxygen-carrying capacity may fall without a significant change in viscosity, and above this, viscosity may increase out of proportion to oxygen-carrying capacity. Despite this evidence, however, recent clinical trials have suggested that a lower hematocrit goal may be appropriate.

In 1999, the Canadian Critical Care Trials Group published the results of the “Transfusion Requirement in Critical Care” (TRICC) study, an investigation of 838 ICU patients who were randomized to a “restrictive” (trigger Hb 7.0 g/dL, target Hb 7.0 to 9.0 g/dL) or “liberal” (trigger Hb 10.0 g/dL, target 10.0 to 12.0 g/dL) strategy.⁹⁰ Overall, hospital mortality was decreased in the “restrictive group,” whereas 30-day mortality was similar between the two groups. Patients who were less acutely ill (APACHE-II score < 21) or younger (< 55 years) had a significantly lower mortality with a “restrictive” transfusion strategy, whereas patients with clinically significant cardiac disease (unstable angina, myocardial infarction)⁹¹ had a higher mortality rate with the “restrictive” strategy. Only a small subset of these patients had moderate or severe TBI, but a subgroup analysis of these patients also revealed no significant difference in outcome between a

“restrictive” or “liberal” strategy (this analysis was limited in power because of small patient groups).⁹² A retrospective review of 169 patients with severe TBI found that number of days with hematocrit less than 30% was associated with improved neurologic outcome, although very low levels were associated with worse outcome.⁹³ In this study, administration of a blood transfusion was associated with worse outcome. Others have suggested that outcome may be associated with the age of blood; a recent study by Leal-Noval and colleagues found that packed red blood cell units that have been banked for less than 19 days have more favorable effects on cerebral oxygenation following severe TBI.⁹⁴

At present, the “ideal” hematocrit for patients with severe TBI is not known and may lie between 21 and 30%.

Spinal Cord Injury

DIAGNOSIS AND INITIAL MANAGEMENT

In the field, all patients with significant trauma, any trauma patients who lose consciousness, and any patients suffering minor trauma who have complaints referable to the spine or the spinal cord should be treated as if they had an SCI until proven otherwise [see Figure 4]. If cardiopulmonary resuscitation is necessary, it takes precedence. The objectives are to maintain adequate oxygenation and maintain blood pressure (BP) by administering fluids and vasopressors. The main concerns of management in the field are immobilization before and during extrication from a vehicle (or removal from the scene of another type of accident) and immobilization during transport to prevent active or passive movement of the spine. Subsequently, the patient may require a rigid Philadelphia collar, support from sandbags and straps, a spine board, or a log-roll for turning. A brief motor examination may detect possible deficits.

When the patient arrives at the hospital, care should be taken to provide adequate oxygenation, prevent hypotension, and maintain immobilization. Patients with an injury above C4, who may have respiratory compromise, may need ventilatory assistance. Lesions above T5 may be accompanied by loss of sympathetic tone and ensuing venous pooling and arterial hypotension. Because paralytic ileus is common, usually lasting several days, a nasogastric tube should be placed to prevent vomiting and aspiration. A Foley catheter should be inserted because urinary retention is also a common occurrence. Vasomotor paralysis may cause poikilothermia (uncontrolled temperature regulation), and normothermia should therefore be maintained.

A detailed neurologic examination is required to determine whether the injury is complete or incomplete and at what level of the spinal cord the injury occurred. If possible, a history should determine the mechanism of injury (e.g., hyperflexion, extension, axial loading, or rotation). The American Spinal Injury Association (ASIA) (www.asia-spinalinjury.org) has developed a protocol for sensory and motor examination of patients with SCIs that is precise and relatively easy to follow [see Figure 5].

Spinal shock consists of loss of all or most motor, sensory, and autonomic functions below the level of the lesion. It usually develops in the setting of a severe SCI that occurs over a brief

Figure 4 AP = anteroposterior; ATLS = advanced trauma life support; BP = blood pressure; CT = computed tomography; MAST = military antishock trousers; MRI = magnetic resonance imaging; NG = nasogastric.

period and is most commonly witnessed immediately after the injury (although it may also appear hours later in cases of progressive injury). As originally defined, the term “spinal shock” referred to arterial hypotension resulting from loss of sympathetic tone after SCI. Currently, however, most authors use the term to refer to the complex of symptoms associated with the loss of spinal reflex activity below the level of the lesion, which

may or may not include arterial hypotension. The motor component of spinal shock may consist of paralysis, flaccidity, and areflexia. The sensory component may involve both spinothalamic and dorsal column sensory function, and the autonomic component may include systemic hypotension, bradycardia, skin hyperemia, and warmth.

Spinal shock should be differentiated from spinal concussion. Spinal concussion is a poorly understood phenomenon. It is defined as partial spinal cord sensory or motor deficits that resolve completely within 24 to 72 hours and that are never associated with permanent SCI. Spinal concussion is rare and has never been described in conjunction with spinal shock.

All patients with possible spine injuries should be examined radiologically. Roentgenography of the cervical spine with the patient in a rigid collar includes a lateral view showing both the craniocervical and the cervicothoracic (C7 to T1) junction. If the lateral view is normal and the patient is coherent and has no neck tenderness or neurologic deficit, the collar can be removed for anteroposterior and odontoid views. If the lower cervical spine or the cervicothoracic junction is not well visualized, a lateral view with caudal traction on the arms, or a swimmer’s view, is required. If areas of the spine are still not visualized or if there is a neurologic deficit, a CT scan with sagittal reconstruction should be obtained through the poorly visualized levels.

The use of flexion-extension films (i.e., testing of the active range of motion of the cervical spine from maximal anteroposterior flexion to extension) is typically limited to patients who are awake and able to cooperate.⁴⁵ Although spinal instability is probably best demonstrated with this type of imaging, it should be noted that in patients with neck pain, muscle spasm can limit range of motion and thereby mask a subluxation. Accordingly, it is recommended that patients with posttraumatic neck pain who are neurologically intact, whose plain radiographs are normal, and who are capable of limited flexion and extension effort (i.e., < 30° of motion) be placed in a rigid cervical collar and reevaluated 1 to 2 weeks later. In comatose patients, dynamic films are sometimes obtained under direct fluoroscopic guidance, although magnetic resonance imaging (MRI) appears to render such studies unnecessary.

CT is particularly helpful in the further evaluation of fractures diagnosed on plain films: it shows bone in greater detail and at higher resolution than plain films or MRI. It achieves better visualization of fixed subluxations and allows more accurate assessment of the central bony canal and the neuronal foramina. CT is highly accurate in visualizing body fractures, Jefferson (C1) and hangman (C2) fractures, and bilateral locked facets. It appears to be less accurate, however, in visualizing transverse C2, posterior element, and nondisplaced spinous process fractures and sometimes misses superior articular process fractures.⁹⁵

MRI of the cervical spine is the study of choice for evaluating injury to the soft tissues and ligaments. Intrinsic cord damage (e.g., edema, hematoma, or contusion) and injury to the surrounding ligaments, disks, and paravertebral soft tissues are well visualized. In addition, MRI is helpful in the assessment of brachial plexus injury, although a series of special coronal images is usually required. A fat suppression image usually identifies ligamentous injury to the posterior elements quite well, and fine-cut gradient echo imaging of the

transverse ligament of C2 is extremely sensitive in detecting disruption.⁹⁶ The major drawbacks of MRI are the length of the imaging time, which may be a problem in the critically ill trauma patient, the susceptibility to movement artifacts, and the need for MRI-compatible monitoring devices and traction equipment. Moreover, in this setting, it is often difficult to obtain an adequate medical history with regard to implanted medical devices or old bullet fragments, both of which preclude MRI. Radiologic evaluation and clearance of the cervical spine can be facilitated by the use of an established protocol [see Figure 6].

Anteroposterior and lateral views of thoracic and lumbosacral vertebrae should be obtained for all trauma patients who were thrown from a vehicle or fell more than 2 meters to the ground, complain of back pain, are unconscious, cannot reliably describe back pain or have altered mental status preventing adequate examination, or have an unknown mechanism of injury or other injuries that suggest the possibility of spinal injury. If a fracture or subluxation is

found on the plain films, a CT scan with sagittal reconstruction extending from one level above the fracture or subluxation to one level below it is recommended.

Indications for urgent MRI include the following: an incomplete lesion with normal alignment (to rule out the possibility of compression); deterioration (worsening deficit or ascending level); a fracture level different from the level of deficit; and neurologic deficit but inability to identify a bony injury on CT (to rule out the possibilities of soft tissue compression, disk herniation, or hematoma that would necessitate surgery). Radiologic evaluation of patients with suspected thoracolumbar spine injuries is also facilitated by use of a protocol [see Figure 7].

In most patients, the spine can be cleared on the basis of plain x-rays and neurologic examination. Obtunded or comatose patients whose plain x-rays are normal but who are at high risk for spine injury (e.g., those injured in high-speed motor vehicle accidents or by falls from great heights) should be evaluated by a spine specialist before spine clearance.

03/10

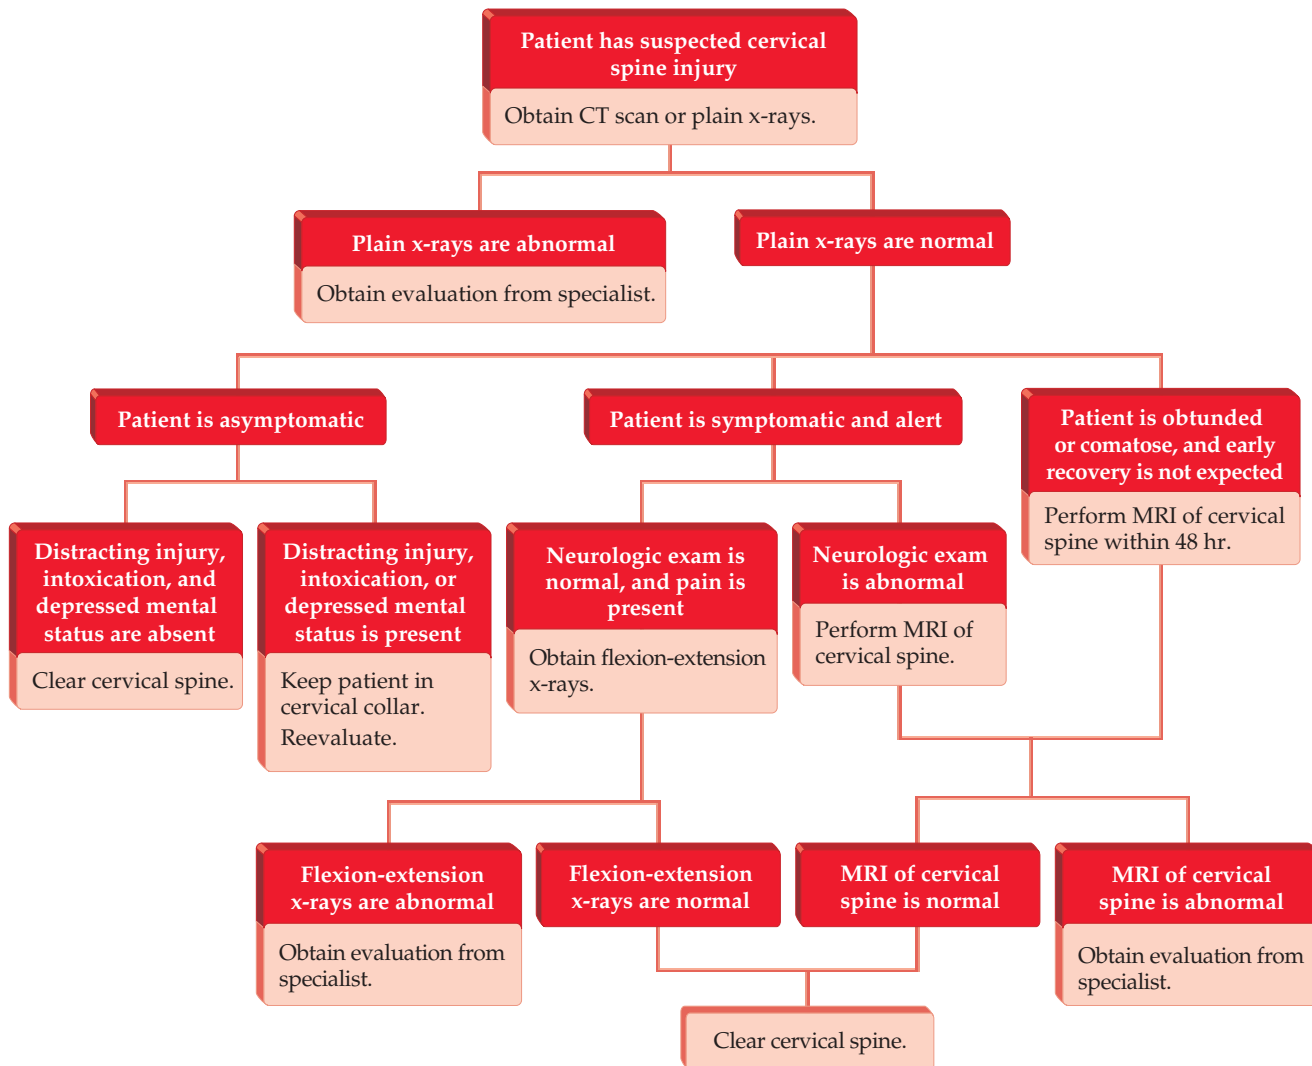

Figure 6 CT = computed tomography; MRI = magnetic resonance imaging.

TREATMENT

Traction

The objectives of craniocervical traction are to reduce fracture-dislocations, to maintain normal alignment or immobility of the cervical spine to prevent further injury, to decompress the spinal cord and roots, and to facilitate bone healing. A common technique is placement of Gardner-Wells tongs, a U-shaped device with pins that are anchored to the skull just above the pinna. Traction is applied with the patient in the supine position by adding weights to the traction ring. Alternatively, traction may be applied with the patient in a halo ring. A special traction triangle is then added to the ring. The advantage of this approach is that the patient can be stabilized in a halo vest as soon as reduction is obtained. Furthermore, the halo vest is helpful in dealing with a highly unstable spine that requires instrumentation because the patient can be easily turned onto the operating table without the risk of significant movement of the spine.

Traction should always be applied under strict neurologic monitoring. If the patient's condition deteriorates when the weight is increased, additional weight should be removed and the patient should immediately undergo imaging (e.g., with plain films, MRI, or both). In the case of a highly unstable fracture, traction should be guided by fluoroscopy rather than serial x-rays.

Pharmacologic Treatment

A number of drugs are known to interfere with the processes of secondary injury. The challenge is to identify the most effective treatment or combination of treatments with the fewest severe side effects—a task requiring many experiments for each treatment tested. Methylprednisolone (MP), thought to act by scavenging free radicals, has been reported to be neuroprotective in patients with SCIs.^{97–99} Considerable controversy remains, however, regarding the clinical benefit of MP administration after acute SCI.

Three multicenter, randomized, controlled clinical trials carried out in the United States evaluated MP in this setting:

Figure 7 CT = computed tomography; MRI = magnetic resonance imaging.

the National Spinal Cord Injury Study (NASCIS) I, NASCIS II, and NASCIS III.⁹⁷⁻⁹⁹ In NASCIS I, reported in 1984, the administration of a 100 mg MP bolus followed by 100 mg/day for 10 days was compared with administration of a 1,000 mg MP bolus followed by 1,000 mg/day for 10 days. There was no placebo group. No difference was noted between the two MP groups with respect to motor or sensory outcome at 6 weeks, 6 months, and 1 year.

Because data from animal studies suggested that the MP doses used in NASCIS I were too low to yield a significant difference in outcome, NASCIS II was initiated in 1985. In this trial, administration of high-dose MP (i.e., a 30 mg/kg bolus followed by 5.4 mg/kg/hour for 23 hours) was compared with administration of naloxone (a 5.4 mg/kg bolus followed by 4 mg/kg/hour for 23 hours) and with placebo. Neurologic outcome was graded by evaluating sensory and motor function at 6 weeks and 6 months after injury. Fourteen muscle groups were examined and graded on a scale of 0 to 5. The scores were added, with a total score

of 0 indicating no motor activity below the level of the lesion and a total score of 70 representing normal motor function. For sensory assessment, 29 spinal cord segments were similarly evaluated and graded on a scale of 1 to 3. A total score of 29 indicated no response in any segment, and a total score of 87 indicated that all sensory segments were normal. The authors reported a statistically significant mean motor and sensory improvement after MP administration. In the MP group, there was a mean improvement of 16.0 in the motor score, compared with a mean improvement of 11.2 in the placebo group. The mean changes in sensory scores were 11.4 (MP) and 6.6 (placebo) for sensation to pinprick and 8.9 (MP) and 4.3 (placebo) for sensation.

In NASCIS III, patients who received a 24-hour regimen of MP (a 30 mg/kg bolus followed by 5.4 mg/kg/hr), a similar 48-hour regimen, or a 48-hour regimen of tirilazad mesylate (2.5 mg/kg every 6 hours) were evaluated. There was no placebo group. No differences in sensory or motor recovery were observed between groups. In a subgroup analysis, it was noted that in patients whose treatment was initiated more than 3 hours after injury, motor function improved more with the 48-hour MP regimen than with the 24-hour regimen. The Functional Independence Measurement (FIM) did not show any statistically significant differences between groups.

NASCIS II and III have been criticized for flaws in research design and data analysis. For example, patients with a normal motor examination and patients with a combined conus-cauda injury were included. Furthermore, only motor and sensory scores from the right side of the body were reported. Moreover, in the statistical analysis, only the results of a post hoc analysis were statistically significant.

A 2000 study presented a statistical reanalysis of the NASCIS II and III data.¹⁰⁰ In this reanalysis, no difference in neurologic recovery between the placebo, 24-hour MP, and 48-hour MP groups was found, but an increased mortality was documented in the 48-hour MP group—a finding that was not reported in the NASCIS studies. Current guidelines take the position that the available medical evidence does not conclusively establish the existence of a significant clinical benefit from administration of MP for either 24 or 48 hours and that the harmful side effects may actually outweigh any clinical benefits.¹⁰¹ MP administration is therefore considered a treatment option to be used at the discretion of the treating physician.

The calcium channel blocker nimodipine causes significant increases in blood flow in the spinal cord,^{102,103} but, paradoxically, the dosage necessary to exert this effect is accompanied by significant systemic hypotension. Administration of GM₁ ganglioside, a compound that occurs naturally in the membranes of mammals and is particularly abundant in the central nervous system (CNS), has been shown to have short-term neuroprotective effects and long-term regenerative effects in animal models. In a prospective, placebo-controlled, double-blind study, some improvement in motor, sensory, and bladder function was seen in patients treated with GM₁ ganglioside, but no overall improvement in neurologic outcome was noted.¹⁰⁴ This agent is currently an optional treatment for patients with SCIs. Treatment with GM₁ ganglioside is started after the completion of MP therapy and continued for 56 days.

Surgical Treatment

The role of neurosurgery in the treatment of spinal fractures and SCI remains controversial. There is considerable disagreement as to whether surgery should be performed, what type of surgery, and when. The primary goals of treatment are to decompress and protect underlying neural structures, to restore spinal stability and alignment, to facilitate early mobilization and rehabilitation, and to maximize neurologic recovery.

There is general agreement among physicians that immobilization of the patient to prevent further injury and early stabilization of fractures and dislocations of the spine are necessary. The single widely accepted indication for early urgent surgical treatment is ongoing neurologic deterioration in the presence of spinal canal compromise from bone and disk fragments, hematoma, or unreduced subluxation. Surgical indications still under debate include incomplete SCI (with persistent spinal cord compression) and complete SCI with the possibility of some neurologic recovery.

In some studies, early surgical intervention has been associated with an increased risk of systemic complications (especially pulmonary complications) and neurologic deterioration. One group of investigators found that one third of all cases of neurologic deterioration could be attributed directly to surgical intervention; four of 26 patients who underwent spinal surgery within 5 days experienced deterioration, whereas none of the patients treated after 5 days had any neurologic sequelae.¹⁰⁵

Other studies, however, have not found an increased risk of deterioration with early intervention. One study evaluated 110 patients with cervical SCI, of whom 88 underwent surgery for spinal stabilization; in the 39 patients treated within 24 hours, the incidence of systemic complications was reduced by 50% in comparison with the incidence in the 49 patients treated 24 hours to 3 weeks after injury.¹⁰⁶ In addition, the incidence of neurologic deterioration was 0% in the early-stabilization group compared with 2.5% in the late-stabilization group. Data from NASCIS II showed improved outcome in patients undergoing surgery within 24 hours of injury compared with patients treated after 200 hours, but the difference was not statistically significant.¹⁰⁷

We adhere to the following protocol in treating patients with cervical spine fracture-dislocations. After systemic stabilization, patients are placed in a halo ring and traction as soon as possible. We prefer to set up traction in the neurologic ICU, but this can be done in the emergency department when necessary. Closed reduction is attempted under the guidance of fluoroscopy or serial x-rays, depending on the degree of spinal cord compromise or expected instability. Patients are then secured in their halo vests and undergo MRI evaluation, regardless of whether reduction attempts succeeded or failed. Patients with reduced and realigned injuries and no cord compromise are kept in their halo vests and offered nonurgent surgical stabilization, depending on the nature of the injury. Patients with irreducible fractures or continued compromise of the neural elements are taken to the OR promptly for urgent surgical decompression and fixation, regardless of whether the neurologic injury is complete or incomplete.

The efficacy of early surgical decompression in patients with thoracolumbar fractures is not established, except in cases where the neurologic examination reveals deterioration. Most surgeons, however, advocate urgent decompression in patients who have canal compromise and an incomplete injury; patients who do not fall into this category can be kept on strict spinal precautions, with definitive therapy instituted on a nonurgent basis.

Diagnosis and Treatment of Specific Fractures and Dislocations

Cervical spine Injuries to the cervical spine include atlas fractures, axis fractures, fractures of the lower cervical spine, and atlanto-occipital and atlantoaxial dislocations. Atlanto-occipital dislocation (AOD) is rare, occurring in approximately 1% of patients with cervical spine injuries. Many of these patients die immediately after trauma as a result of brainstem injury and respiratory arrest. Since the 1980s, advances in emergency patient management in the field, reduced transport time, and better recognition of the condition have improved the survival rate after AOD. Nevertheless, since 1966, fewer than 100 survivors of AOD have been reported in the literature. Patients who survive AOD often have neurologic deficits, such as lower cranial neuropathies, unilateral or bilateral weakness, and quadriplegia. Some 20% of patients, however, exhibit no abnormalities on neurologic examination at presentation. AOD is difficult to diagnose and is often missed on the initial cervical radiograph. Accordingly, a high index of suspicion for this condition should be maintained, particularly when signs such as prevertebral soft tissue swelling on the plain cervical radiograph or subarachnoid hemorrhage at the craniovertebral junction on CT are present. Additional investigation with MRI may be necessary.

Because AOD mostly involves ligamentous injury, treatment generally consists of operative fusion. Traction is rarely employed because even a small weight may cause distraction injury with these highly unstable dislocations.

Atlantoaxial dislocations are often fatal as well. Like AODs, they are highly unstable lesions associated with severe ligamentous injury.

Atlas (Jefferson, or C1) fractures, which represent 5 to 10% of all cervical spine fractures, result from axial loading. Because of the large diameter of the spinal canal and the tendency of fragments to move outward, these fractures usually are not accompanied by significant neurologic injury. However, 40% of patients with an atlas fracture have another cervical fracture as well (usually involving C2). The integrity of the transverse ligament largely determines whether the fracture is stable.¹⁰⁸ Injuries that involve the midportion of the transverse ligament or the periosteal insertion (e.g., types Ia and Ib) will not heal spontaneously and must be treated with surgical fixation of the C1-C2 complex. In contrast, type II injuries (e.g., avulsion injuries or comminuted lateral mass fractures) will usually heal in a rigid external orthosis (e.g., a halo vest). Most other atlas fractures can be managed in a rigid cervical collar, except for widely displaced or comminuted fractures, which also require that the patient be immobilized in a halo vest.

Axis (C2) fractures account for 10 to 20% of all cervical spine fractures in adults and 70% of cervical fractures in

children. The odontoid process is the part of C2 that is most commonly fractured (accounting for 60% of axis fractures). The management of odontoid fractures remains controversial: only class III data are available, which are insufficient to establish practice guidelines.¹⁰⁹

Three different types of odontoid fractures are recognized. Fractures of the tip of the odontoid process (avulsion fracture, type I) are uncommon but are thought to be stable in most cases. They can be treated by using a hard cervical collar with or without preceding cervical traction or by immobilizing the patient in a halo vest.

Fractures of the neck (type II) and fractures at the junction of the odontoid process and the axis body (type III) are more common (accounting for 65 to 80% and 20 to 35% of odontoid fractures, respectively). Management of type II fractures depends on the degree to which the dens is displaced: fractures with more than 5 mm of displacement are typically managed surgically, whereas fractures with less than 5 mm of displacement can be treated nonsurgically with a halo vest or a semirigid orthosis (e.g., a sterno-occipito-mandibular immobilizer [SOMI] brace).¹¹⁰ The management of type II fractures also depends on the age and general medical condition of the patient. Halo-vest immobilization is associated with a significantly increased risk of pulmonary complications and death in elderly patients and thus should be used with caution in this population. Surgical stabilization and fusion are recommended for type II fractures in patients older than 50 years.¹¹⁰

The type IIa subcategory of odontoid fracture warrants special mention. These fractures have either anterior or posterior chip-fracture fragments at the base of the dens and are considered unstable. They are often widely displaced and have a nonunion rate of 75 to 85% with halo-vest immobilization. Accordingly, surgical management is recommended. The integrity of the transverse ligament should be evaluated in patients with type II injuries; fixation with an odontoid screw is contraindicated, and C1-C2 fixation should be performed instead.

Most type III odontoid fractures will fuse with rigid external mobilization (i.e., either cervical traction followed by placement in a rigid cervical collar or placement in a halo vest). Again, more than 5 mm of displacement is an indication for surgical stabilization.¹¹⁰

Traumatic spondylolisthesis, or hangman's fracture, accounts for approximately 20% of C2 fractures. Injury usually results from axial compression in combination with hyperextension of the occipitoatlantoaxial complex on the lower spine, resulting in bilateral fracture of the pars interarticularis. Fractures affecting the ring of the axis without C2-C3 angulation are stable and can be treated with immobilization in a Philadelphia collar or a SOMI brace. Halo-vest immobilization is recommended in unreliable patients or patients with both C1 and C2 fractures. The average healing time is 12 weeks. Fractures with angulation, subluxation, or C2-C3 locked facets are treated with halo-vest immobilization if they are adequately reducible and with surgical intervention if they are nonreducible, are associated with disruption of the C2-C3 disk space, or are subject to recurrent subluxation.^{96,110}

Approximately 80% of all fractures of the lower cervical spine are produced by indirect forces. The vertebra most

commonly involved is C5, and dislocations are most frequent at the C5-C6 level. The following injury mechanisms are observed: flexion and distraction (approximately 40% of cases), flexion and compression (22%), vertical compression (8%), extension and compression (24%), extension and distraction (6%), and lateral flexion (3%).

Flexion and distraction injuries usually result from a blow to the occiput from below. The initial disruption is within the posterior ligamentous complex, leading to facet dislocation and an abnormally large divergence of the spinous processes. Unilateral facet dislocation and facet interlocking result when a rotatory component is involved. Bilateral facet dislocation with anterior translation of the superior vertebra results from severe hyperflexion; the translation is usually at least 50% in such cases. Cord and root involvement vary with the degree of subluxation and translation: 50% of patients with unilateral facet dislocation present with moderate cord and root injury, and 90% of patients with bilateral facet dislocation and a full translation of the vertebral body have a neurologic deficit (most often a complete cord lesion). Teardrop fractures (characterized by a bone chip just beyond the anterior inferior edge of the vertebral body) result from severe hyperflexion injury, and the fractured vertebra is usually displaced posteriorly on the vertebra below; these patients are often quadriplegic.

Flexion and compression injuries, usually observed at the C4-C5 and C5-C6 levels, typically result from a blow to the back of the head. The effect on the anterior vertebral body varies from a moderate rounding or loss of anterior height to a wedge shape with an oblique fracture from the anterior surface to the inferior subchondral plate. Approximately 50% of patients with the latter type of injury have a neurologic deficit. More severe injuries are accompanied by translation of the inferior posterior margin of the vertebral body into the neural canal. About 75% of patients have neurologic involvement. Translations of more than 3 mm result in a complete spinal cord lesion in most cases.

Extension and compression injuries are usually caused by a blow to the forehead and result in fractures of the posterior complex. About 40% of patients with unilateral vertebral arch fractures (articular process, pedicle, or lamina) have a neurologic deficit (most often a radiculopathy). Bilaminar fractures are accompanied by a complete cord lesion in 40% of cases. Bilateral vertebral arch fractures with complete anterior translation of the vertebral body present with radiculopathy (30% of cases), central cord syndrome (30%), or an incomplete cord lesion (30%). In one series, no complete cord lesions were observed with this type of injury.¹¹¹

Treatment of injuries to the lower cervical spine has not been standardized. As a general rule, severe ligamentous involvement and severe vertical compression call for surgical intervention. Severely comminuted vertebral body fractures may also necessitate surgery because of the high risk of progressive kyphosis. Isolated spinous process fractures and unilateral lamina and pedicle fractures are usually managed conservatively with placement in a rigid cervical collar. If there is a fracture through the transverse foramen above C6, the vertebral artery should be evaluated for dissection by means of magnetic resonance angiography, CT angiography,

or catheter angiography.¹¹⁰ Surgical intervention should be carefully considered, especially in young trauma victims. In a series from 1988, 87% of patients with distractive flexion injury and 88% of those with compressive flexion injury healed with halo-vest immobilization.¹¹²

Thoracolumbar spine Approximately 64% of fractures of the spine occur at the T12-L1 junction, and 70% of these fractures are unaccompanied by immediate neurologic injury. Evaluation according to Denis's three-column principle [see Figure 8] is useful for determining whether a fracture is stable, although the precise definition of stability remains controversial.¹¹³ Fractures of the thoracic spine are more stable because of support from the surrounding rib cage and the strong costovertebral ligaments. When two of the three columns are affected, the fracture is considered unstable, and surgical intervention is generally required.

The four major types of thoracolumbar spine injuries are compression fractures, burst fractures, seat-belt fractures (Chance fractures), and fracture-dislocations. These four types of fracture involve the anterior, middle, and posterior columns

of the spine in different ways [see Table 3]. Transverse process fractures are rarely unstable and are typically managed conservatively with analgesics or muscle relaxants.

Minimal to moderate compression fractures (< 50% loss of height or < 30° of angulation) with an intact posterior column can be treated with analgesics and bed rest. Ambulation should be started early, and depending on the degree of kyphosis, external immobilization (with a thoracolumbar orthosis or a Boston brace) may or may not be indicated. Severe compression injuries should be treated with external immobilization in extension. If the loss of anterior height of the vertebral body exceeds 50%, there is an increased risk of progressive kyphosis; evaluation with follow-up radiographs is indicated. Occasionally, surgical intervention is required. An anterior injury is considered unstable if it involves more than three adjacent elements or if height loss in a single element exceeds 50% with more than 30° of angulation.¹¹⁴

Burst fractures are considered unstable even if there is no initial neurologic deficit. Early ambulation should be avoided because the axial loading may result in progressive collapse or angulation, with concomitant neurologic damage. Indications

Figure 8 If two or more columns are destroyed or nonfunctional, instability is likely.

Table 3 Column Failure in the Four Types of Major Thoracolumbar Spinal Injury¹¹³

Fracture Type	Anterior Column	Middle Column	Posterior Column
Compression	Compression	Intact	Intact, or distraction if severe
Burst	Compression	Compression	Intact, or involved
Seat belt	Intact or mild compression of 10–20% of anterior vertebral body	Distraction	Distraction
Fracture-dislocation	Compression, rotation, shear	Distraction, rotation, shear	Distraction, rotation, shear

for the surgical treatment of burst fractures include the following:

1. Loss of more than 50% of body height
2. Retropulsed bony fragments narrowing the canal by more than 50%
3. Kyphotic angulation of 25° or more

A Chance fracture is a horizontal fracture through all three columns. It occurs most commonly in the lower lumbar spine and is a highly unstable injury. Chance fractures are now less frequent than they once were because of the widespread use

of shoulder belts in addition to lap belts, which prevents upper torso flexion during deceleration. Chance fractures are treated with surgical stabilization, and decompression and correction of spinal alignment may be required as well.¹¹⁴

Fracture-dislocations, also known as fracture subluxations, are three-column injuries that usually involve disruption of the ligamentous structures or the disk space. Dural lacerations and neurologic injury are common with such injuries. Fracture-dislocations are considered unstable and are treated with surgical decompression and stabilization.

Discussion

Pathophysiology

HEAD INJURY

Cerebral Metabolism

At 1,200 to 1,400 g, the brain accounts for only 2 to 3% of total body weight and does not do any mechanical work, yet it receives 15 to 20% of all cardiac output to meet its high metabolic demands. Of the total energy generated, 50% is used for interneuronal communication and the generation, release, and reuptake of neurotransmitters (synaptic activity); 25% is used for maintenance and restoration of ion gradients across the cell membrane; and the remaining 25% is used for molecular transport, biosynthesis, and other, as yet unidentified, processes.

Cell metabolism involves the consumption of adenosine triphosphate (ATP) during work and the ensuing consumption of metabolic substrates to resynthesize ATP from adenosine diphosphate (ADP). ATP is generated both in the cytosol (via glycolysis) and in the mitochondria (via oxidative phosphorylation). Glucose is the sole energy substrate, unless there is ketosis, and 95% of the energy requirement of the normal brain comes from aerobic conversion of glucose to water and CO₂. ATP generation is highly efficient. Glycolysis and subsequent oxidative phosphorylation result in the generation of 38 molecules of ATP for each molecule of glucose:

In the absence of oxygen, anaerobic glycolysis can proceed, but energy production is much less efficient. Two molecules

of ATP and two molecules of lactate are generated for each molecule of glucose:

Regulation of Blood Flow

Because the reserves of glucose and glycogen within the astrocytes of the brain are limited and there is no significant storage capacity for oxygen, the brain depends on blood to supply the oxygen and glucose it requires. More specifically, substrate availability is determined by its concentration in blood, flow volume, and the rate of passage across the blood-brain barrier.

Under normal circumstances and with certain physiologic alterations, an adequate supply of substrates can be maintained by regulation of CBF. CBF increases with vasodilatation and decreases with vasoconstriction. Caliber changes take place mainly in cerebral resistance vessels (i.e., arterioles with a diameter of 300 µm down to 15 µm).¹¹⁵ Control of CBF by influencing vessel caliber is commonly referred to as autoregulation of blood flow.

Metabolic autoregulation CBF is functionally coupled to cerebral metabolism, changing proportionally with increasing or decreasing regional or global metabolic demand. Thus, the brain precisely matches local CBF to local metabolic needs. Because 95% of the energy in the normal brain is generated by oxidative metabolism of glucose, CMRO₂ is considered to be a sensitive measure of cerebral metabolism. The relation between CBF and metabolism is expressed in the Fick equation:

$$\text{CMRO}_2 = \text{CBF} \cdot \text{AVDO}_2$$

CMRO₂, expressed in milliliters per 100 g of brain tissue, is normally about 3.2 mL/100 g/min in awake adults. The average CBF value for mixed cortical flow is 53 mL/100 g/min in a healthy adult. AVDO₂, a measure of cerebral oxygen extraction, can be calculated by subtracting the oxygen content of jugular venous blood (6.7 mL/dL) from that of arterial blood (13 mL/dL), resulting in a value of 6.3 mL/dL; this value can then be corrected for hemoglobin content according to the formula discussed earlier [see Head Injury, ICU Management, *above*]. Under conditions of increasing metabolic demand (increased CMRO₂), such as seizures or fever, CBF increases proportionally, thus keeping AVDO₂ constant. With decreasing metabolism (anesthesia, deep coma), CBF decreases.

Pressure autoregulation Another important physiologic property of the cerebral circulation is maintenance of a constant supply of substrates at the level set by metabolism. According to the Poiseuille equation,

$$CBF = k \frac{CPP \cdot d^4}{(8 \cdot l \cdot v)}$$

in which k is a constant of proportionality, d is vessel diameter, l is vessel length, and v is blood viscosity; changes in CPP (e.g., arterial hypotension or increases in ICP) are followed by changes in CBF, unless diameter regulation (pressure autoregulation) takes place.¹¹⁶ In humans, the limits of pressure autoregulation range from 40 to 150 mm Hg of CPP.

Viscosity autoregulation In accordance with the Poiseuille equation, CBF can vary with changes in the viscosity of blood. Blood viscosity changes with variations in hematocrit, γ -globulin, and fibrinogen components of plasma protein. Increased viscosity would increase cerebrovascular resistance ($8 \cdot l \cdot v/d^4$). By means of diameter adjustment (viscosity autoregulation), cerebrovascular resistance is decreased and CBF can be kept constant.¹¹⁷

CO₂ reactivity Vascular caliber and CBF are also responsive to changes in Paco₂. CBF changes 2 to 3% for each mm Hg change in Paco₂ within the range of 20 to 60 mm Hg. Hypercarbia (hypoventilation) results in vasodilatation and higher CBF, and hypocarbia (hyperventilation) results in vasoconstriction and lower CBF. Autoregulation is a compensatory or adaptive response adjusting CBF to metabolism; with CO₂ variation, vessel caliber changes and CBF follow passively. The vessels respond not to changes in Paco₂ but to the pH in the perivascular space. CO₂ can cross the blood-brain barrier freely, thus changing the pH, but over 20 to 24 hours, with a constant new level of Paco₂, the pH in blood and in the perivascular space returns to baseline, and the diameter of the cerebral blood vessels also returns to baseline.¹¹⁸ With CO₂ reactivity, changes in CBF are compensated for by changes in AVDO₂, so that a constant supply of substrates is maintained at the level set by metabolism (CMRO₂). A constant AVDO₂ is a common feature of metabolic, pressure, and viscosity autoregulation; because CBF is tuned to metabolism, AVDO₂ can be kept constant.

Cerebral Circulation and Metabolism after Severe Head Injury

Arterial hypoxia and hypotension It is known from eyewitness reports of head injury and experimental studies immediately after the impact that arterial hypotension and interruption of normal respiration, sometimes with a period of prolonged apnea, are common findings. In the days after a head injury, there are many occasions and opportunities for hypoxic and hypotensive insults. As noted above, hypotension (systolic BP < 90 mm Hg) and hypoxia (Pao₂ < 60 mm Hg) are major determinants of poor outcome.

The effect of hypotension on the brain depends on the status of autoregulation. If autoregulation is defective, decreased BP leads directly and linearly to a reduction in CBF. If autoregulation is intact, arterial hypotension can lead to a considerable increase in ICP, which interferes with CBF by decreasing perfusion pressure.

Elevated ICP According to the Monro-Kellie doctrine, ICP is governed by three factors within the confines of the skull: brain parenchyma plus cytotoxic edema, CSF plus vasogenic edema, and CBV. When the volume in one compartment increases, ICP increases unless there is a compensatory decrease in volume in the other compartments. The relation between intracranial volume and ICP is expressed in the pressure-volume index (PVI).¹¹⁹ PVI is defined by the volume that must be added to or withdrawn from the craniospinal axis to raise or decrease ICP 10-fold:

$$PVI = \frac{\Delta V}{\log ICP_i / ICP_o}$$

where ΔV is the change in volume, ICP_o is ICP before the volume change, and ICP_i is ICP after the volume change. PVI is thus a measure for the compliance ($\Delta V/\Delta P$) or tightness of the brain. Under normal circumstances, PVI is 26 ± 4 mL; 26 mL of volume will raise ICP from 1 to 10 mm Hg, but the same volume will also raise ICP from 10 to 100 mm Hg. Conversely, a change in volume of only 6.4 mL is necessary to increase ICP from 10 mm Hg (normal) to the treatment threshold of 20 mm Hg. Thus, small changes in volume have a relatively large effect on ICP. PVI values as low as 5 mL have been reported in patients with head injuries.

Apart from mass lesions, ICP typically increases after severe head injury because of cerebral edema. Initial compensation is by displacement of CSF from the cranium, which is visualized in a CT scan of the head as small ventricles and basal cisterns. Subsequent compensation would be by a decrease in CBV, which can be accomplished by means of vasoconstriction.

Relation between vessel diameter, CBV, and ICP The total diameter of the cerebrovascular bed determines CBV. Cerebral veins contain most of the total blood volume, but their diameter and thus their volume are relatively constant. Approximately 20 mL of blood (i.e., one third of total CBV) is located in the cerebral resistance vessels (which range in diameter from 300 μ m down to 15 μ m).¹¹⁸ Because most autoregulatory and CO₂-dependent variations in diameter take place in these vessels, CBV is determined mainly by their diameter. Typically, the diameter ranges from 80 to 160% of baseline, resulting in volume changes between 64 and 256%

of baseline. With a baseline value of 20 mL in the resistance vessels, CBV will range from 13 mL (maximal vasoconstriction) to 51 mL (maximal vasodilatation). Given a PVI of 26, change from maximal vasoconstriction to maximal vasodilatation will be accompanied by an almost 29-fold change in ICP.

CBV, ICP, and CBF CBF and CBV are governed by vascular diameter. Thus, depending on other parameters influencing CBF (such as mean arterial BP, ICP, and blood viscosity), changes in vascular caliber also affect CBF.

Hypocarbica reduces ICP by means of vasoconstriction, consequently improving CPP. However, net CBF is decreased because in the Poiseuille equation, vessel diameter is carried to the fourth power. A randomized clinical trial has shown that preventive hyperventilation retards clinical improvement after severe head injury, perhaps through reduction of CBF to ischemic levels.¹²⁰ However, its rapid effect on ICP is a great advantage in cases of acute neurologic deterioration (e.g., in the presence of an expanding mass lesion before evacuation can take place) and should be reserved for these situations.

There are two methods of reducing ICP by means of vasoconstriction without affecting CBF. The first is to reduce blood viscosity. As can be deduced from the Poiseuille equation, decreasing the blood viscosity will, by itself, lead to vasoconstriction, provided that viscosity autoregulation is intact. With impaired autoregulation, decreased viscosity will result in an increase in CBF but no decrease in ICP. However, this effect can be used to maintain CBF under vasoconstriction with hypocarbica. As discussed above, the effect of mannitol on ICP is thought to be mediated in part by lowering blood viscosity.

The second method of reducing ICP without affecting CBF is to increase CPP, which can be done by raising BP. Again, with intact autoregulation, an increase in CPP will lead to vasoconstriction, with net CBF remaining constant. With impaired autoregulation, CBF will follow CPP passively, and maintenance of normal BP may be indicated in these cases. More important, however, is the avoidance of hypotension under these circumstances; the effect of CPP therapy may be attributable in part simply to prevention of hypotension.

Cerebral ischemia Cerebral ischemia, defined as CBF that is inadequate to meet the metabolic demands of the brain, is an important mechanism of secondary injury in patients with severe head injury, and the adequacy of CBF

has been associated with neurologic outcome. In autopsy findings from patients dying after severe head injury, histologic damage indicative of cerebral ischemia was seen in 80% of cases.¹²¹ One group of investigators found that ischemia (CBF < 18 mL/dL with abnormally high AVDO₂ values) occurred in 20 to 33% of patients with severe head injuries within 4 to 12 hours of injury and that the ischemia was associated with a poor prognosis.¹²² Of the intracranial lesions, acute subdural hematoma and diffuse cerebral swelling were most often associated with ischemia.

The relation between cerebral metabolism and CBF is expressed in the Fick equation [see Metabolic Autoregulation, above]. The normal brain tends to keep AVDO₂ constant and to react to changes in metabolism by adjusting blood flow. When CBF decreases in response to metabolism (as with hyperventilation or decreasing CPP with impaired autoregulation), oxygen supply is maintained by increasing oxygen extraction (i.e., AVDO₂ increases). A rising AVDO₂ is thus a sensitive marker of insufficient cerebral perfusion. However, the extent to which oxygen extraction can be increased is limited, and this limit is reached when AVDO₂ is doubled (13.2 mL/dL). Consequently, any further reduction in CBF results in neuronal dysfunction (i.e., CMRO₂ decreases). Because 50% of the energy is used for synaptic activity, a reversible and functional loss is usually observed first. Further decline, however, will result in ion pump failure, loss of membrane integrity, consequent cell swelling (cytotoxic edema), and cell death (irreversible infarction). The occurrence of irreversible infarction depends on both the level and the duration of ischemia. When CBF falls to approximately 18 mL/100 g/min for more than 4 hours, it reaches the threshold for irreversible infarction.

Maintenance or improvement of CBF is thus essential to the treatment of severe head injury, and AVDO₂ is a sensitive marker of the adequacy of therapy. When therapeutic measures fail to sustain CBF, CMRO₂ can be decreased to reinstate the match between CBF and metabolism. CNS suppression can be achieved by administering hypnotic agents (e.g., barbiturates or propofol) or inducing hypothermia. Decreasing cell metabolism will result in reduced production of CO₂, lactic acid, or both and (with blood vessels almost always remaining responsive to perivascular pH changes) in vasoconstriction accompanied by reductions in both CBF and ICP. The relations between CMRO₂, CBF, CBV, CPP, and AVDO₂ are complicated. An overview is available elsewhere [see Table 4].¹²²

Financial Disclosures: None reported.

Table 4 Changes in CBF, CBV, ICP, and AVDO₂ Associated with Primary Reduction of Selected Variables¹²²

Variable Reduced	CBF	CBV (ICP)	AVDO ₂
CMRO ₂	↓	↓	NC
CPP (autoregulation intact)	NC		NC
CPP (autoregulation defective)	↓	↓	
Blood viscosity (autoregulation intact)	NC	↓	NC
Blood viscosity (autoregulation defective)	↑	NC	↓
Paco ₂	↓	↓	↑
Conductance vessel diameter (vasospasm above ischemia threshold)	↓	↑	↑

AVDO₂ = arteriovenous oxygen content difference; CBF = cerebral blood flow; CBV = cerebral blood volume; CMRO₂ = cerebral metabolic rate of oxygen; CPP = cerebral perfusion pressure; ICP = intracranial pressure; Paco₂ = arterial carbon dioxide tension; NC = no change.

3 INJURIES TO THE FACE AND JAW

Mark E. Engelstad, DDS, MD, and Richard A. Hopper, MD, MS

Assessment and Management of Maxillofacial Injuries

The human face is vulnerable to injury. It is frequently the target of interpersonal violence or inadequately restrained within a motor vehicle accident. Injuries to both the soft tissues and skeleton of the face are frequent sources of emergency department admissions and consultations. Isolated maxillofacial trauma is rarely life threatening or an immediate cause of death unless associated with airway compromise.¹ However, approximately 20% of all patients with facial soft tissue, dentoalveolar, or facial fracture trauma have associated injury to additional body systems.² Motor vehicle crash victims with facial injuries have a high associated rate of neurologic (32%), orthopedic (31%), visceral (24%), and ophthalmologic (14%) injuries. Personal assault has a lower association with neurologic (11%) and ophthalmologic (4%) injuries.³ When facial fractures are present in patients suffering an occupational injury, an average of four associated injuries are seen for every facial fracture present and 2.4 associated injuries for every facial fracture present in a victim of a motorcycle crash.

In the 21st century, facial injuries still result in devastating permanent defects in function and appearance, but advanced craniomaxillofacial (CMF) techniques are steadily improving outcomes. In the past 40 years, techniques in CMF surgery have evolved significantly. Advancement in minimally invasive access, internal fixation with plates and screws allowing immediate function, reconstruction of defects with primary bone grafting and patient-specific implants, and computer-assisted surgical planning are improving results and decreasing treatment time.

It is now widely recognized that a coordinated, multidisciplinary treatment strategy achieves better outcomes for facial trauma patients. CMF trauma patients return to function and a normal quality of life far sooner than when long periods of intermaxillary fixation (IMF) and gruesome external appliances were the norm.

Initial Evaluation

Maxillofacial injuries result from energy transfer that is usually blunt or penetrating in nature. Blunt trauma to the face, most commonly secondary to motor vehicle accidents or assault, results in bony and dental injury, whereas penetrating trauma causes neurovascular injury and soft tissue defects. Gunshot wounds can show surprisingly few external signs of injury while causing extensive damage to the hard tissues of

the face as the bones and teeth absorb energy from the passing projectile. Shotgun wounds result in obvious and extensive avulsion of both hard and soft tissues. Firearm injuries that cause avulsion of large portions of the face are quite survivable if the airway is secured.

Maintaining an airway is the primary consideration in facial trauma. Bony maxillofacial injury does not usually require immediate surgical attention but is a sign that significant force has been sustained and that the cervical spine and airway should be evaluated and monitored.⁴ The surgeon must maintain vigilance because patients who present soon after injury can, over subsequent minutes or hours, lose their airway as edema progresses [see Figure 1].

The initial maxillofacial assessment should include documentation of the presence or absence of vision in each eye. Soft tissue injuries causing significant hemorrhage should be dealt with; palpating the scalp and looking behind the ears and under the cervical collar will reveal hidden lacerations. The facial skeleton should be evaluated for mobility or malocclusion and the oropharynx inspected for loose teeth or foreign bodies that could obstruct the airway.

Assessing the occlusion for changes can be confusing because there are so many normal variants of dental anatomy. If there are step-offs in the dental arch, then a fracture is likely; asking the patient if the bite feels abnormal is also helpful. In the intubated patient, the diagnosis of facial fractures can be delayed, so the patient should be reexamined after extubation. The presence of numbness on the face, especially around the upper and lower lips, is also suggestive of facial fracture.

The initial survey should proceed with the following priorities, in decreasing importance: airway, hemorrhage, vision, bony trauma, soft tissue injuries.

AIRWAY ASSESSMENT

Facial trauma can result in immediate or delayed airway compromise. The caliber of the airway can decrease subsequent to displacement of facial bones, expanding edema or hematoma, loose dentition and debris, foreign bodies, or laryngeal injuries. A heightened level of awareness is needed when monitoring the airway after facial trauma. Most low- to moderate-energy facial trauma does not result in significant airway compromise over time. However, edema from injuries with high-energy transfer, such as gunshot wounds or high-speed blunt trauma, can steadily worsen over time. If the patient feels that he or she must sit up to breathe comfortably, this can be taken as a sign of current or pending airway compromise.

In patients who cannot maintain their own airway, an endotracheal tube should be inserted at the first opportunity, both to maintain ventilation and prevent aspiration. In the

Assessment and Management of Maxillofacial Injuries

Figure 1 This patient suffered a combination of blunt and penetrating trauma to the central face. Note the unstable maxilla, missing bone, endotracheal tube, and intracranial bolt monitor. Clamps had been placed in the field to control arterial bleeding. This patient will require tracheostomy, reduction and fixation of bone fragments, bone grafting of missing bone, and soft tissue reconstruction.

presence of midface and skull base fractures with or without cerebrospinal fluid (CSF) leakage, an airway is more safely established by orotracheal intubation or cricothyrotomy. Both of these routes minimize the likelihood of inadvertent submucosal or intracranial tube placement, as may occur with nasal intubation in the trauma setting. However, nasotracheal intubation is not absolutely contraindicated in the presence of these injuries; the use of fiberoptic intubation techniques can provide safe transnasal endotracheal tube passage. Alternatively, a stylet to maintain the direction of passage, along with direct oropharyngeal visual confirmation of the tube passing over the soft palate, can allow safe nasotracheal intubation. Blind nasotracheal intubation should be avoided in patients with cribriform plate fractures.

Treatment of the compromised airway is complicated by the likelihood that 10% of patients with facial trauma have a cervical spine injury.⁵ A cervical collar or need to maintain in-line traction makes intubation in the emergency setting even more difficult. In the uncooperative trauma patient in need of a safe airway, only a brief attempt should be made to insert an endotracheal tube. If unsuccessful, cricothyrotomy should be performed. If time and urgency allow, a more deliberate tracheotomy may be done instead.

Maxillofacial fractures alone, even when extensive, are not usually an indication for a surgical airway. Internal fixation of maxillofacial injuries minimizes the need for IMF (wiring the upper and lower teeth together) and significantly shortens the recovery period. The decision to accept the morbidity and potential complications from tracheostomy or cricothyrotomy should be based on airway deterioration and inability to intubate or the anticipated need for a long duration of intubation.

MAXILLOFACIAL HEMORRHAGE

Once an airway has been established, the next maxillofacial priority is to control bleeding from the face, scalp, or deeper wounds. Firm compression with moist packs is an effective way to stop most arterial and venous facial bleeding. Definitive ligation or cautery of a single bleeding point is sometimes necessary. Blind clamping and suture ligation in deep wounds should be avoided in areas where the facial nerve may be injured.

Blood loss from scalp laceration, much of which may have occurred at the scene of injury, can be severe enough to cause hypovolemic shock.⁶ Continuous scalp hemorrhage often comes from arteries just superficial to the galea, where they are surrounded by dense connective tissue, which prevents scalp arteries from retracting after injury.⁷ Single-layer suture wound repair or application of Raney clips can minimize scalp blood loss until definitive wound repair is possible.

Persistent nasal hemorrhage is first treated by direct pressure with anterior nasal packing. In the trauma setting, epistaxis may have a number of sources; packing both the anterior and the posterior nasal cavity is sometimes required to provide sufficient direct pressure, but extensive comminution of the midfacial skeleton will make nasal packing less effective. Most commercially available nasal packs involve an anterior balloon and a posterior balloon with separate ports for differential inflation pressures. In a fully mobile Le Fort fracture, IMF may be required to prevent the maxilla from being inferiorly displaced during nasal packing. If packing is ineffective, embolization of the internal maxillary artery (IMA) or facial artery is usually required.⁸

There is a large amount of evidence that early transarterial embolization is the most effective treatment for significant persistent facial hemorrhage that does not respond to direct pressure or other methods.^{8–11} Reduction and fixation of bony injuries are often not effective at controlling significant bleeding. Likewise, ligation of the external carotid artery is unreliable because of the rich collateral vascular supply to the head and face.¹² In unstable patients with ongoing significant facial hemorrhage that cannot be controlled by packing, embolization should be considered as soon as possible.¹³

Comprehensive Survey

In the multisystem trauma patient, maxillofacial injuries have relatively low priority. Unless airway compromise, deteriorating visual acuity, or severe hemorrhage exists, the definitive diagnostic maxillofacial evaluation can be delayed until the stabilization of more life- and limb-threatening injuries. A definitive maxillofacial trauma examination should proceed in a consistent sequence.

INSPECTION

Facial swelling or facial asymmetry is a sign of underlying bony injury. The face can swell quickly and dramatically, even with minimal skeletal injury. Trauma can be hidden in easy-to-overlook areas underneath cervical collars, behind the ears, and in the hair. Look inside the mouth for injured dentition or ecchymosis under the tongue or on the mucosa, which are signs of mandibular or maxillary fracture. If the patient can bite, look for gross malocclusions or step-offs in the dental arch and ask the patient to open and close the mouth.

If the bite feels abnormal to the patient, a mandibular or midfacial fracture is likely [see Figure 2]. Inspect the interior of the nose for CSF leakage, septal deviation, or septal hematoma. Septal hematomas are rare but should be drained to decrease the chance of septal cartilage necrosis and resulting nasal deformity [see Figure 3].

Periorbital ecchymoses are associated with zygomatic, orbital, or skull base fractures; ecchymosis in the mastoid region, the so-called Battle sign, is also a sign of skull base fracture. Facial nerve injuries are initially localized by asking the patient to lift the eyebrows, close the eyes, and purse the lips.

Inspect the external auditory canal and the tympanic membrane for blood or ecchymoses, which are signs of skull base or mandibular condyle injury. Confirm that gross hearing is intact by rubbing your fingertips together near both ears.

Ocular and periorbital evaluation is an important part of the facial trauma examination. If lacerations exist around the eye, closely inspect the lid margin and the nasolacrimal duct for injury; both would require specialized repair. The normal distance between medical canthi in adults is 33 to 35 mm. An increase in this distance is called telecanthus and is a sign of significant bony trauma between the orbits, the so-called naso-orbitoethmoid (NOE) fracture.

Ocular pain, decreased vision, and the appearance of spots before the eyes are all highly suggestive of globe damage. One prospective study reported a 29% incidence of ocular injury in 49 patients with orbital fractures.¹⁴ Gross visual acuity

Figure 2 **Fractured mandible.**

Figure 3 **Fractured zygoma.**

and the presence of diplopia should be assessed for each eye separately and both eyes together. Documentation of acuity (i.e., “can count fingers at 2 meters” or “light perception only”) allows comparison over time and makes detection of progressive visual loss more likely.

Evaluate the eyeball for extraocular movement. Note that in fractures involving the orbit, some decrease in extraocular range of motion is expected; this differs from true inferior rectus muscle entrapment, which prevents any movement in superior gaze and is often accompanied by pain and nausea. Vertical or anteroposterior changes in globe position relative to the other eye are a sign of orbital fracture. Check pupils for symmetry, light reactivity, hyphema (blood in the anterior chamber of the eye), and subconjunctival ecchymoses. If globe disruption is suspected, never press on or around the eye and always protect it from further disruption with a shield.

If the trauma sustained was significant enough to fracture the orbital bones, then the possibility of globe injury exists, even when no external signs of ocular trauma are visible.¹⁵ Although the threshold for requesting an ophthalmology consultation varies by institution, it is absolutely indicated in the presence of decreasing visual acuity, anisocoria not accounted for by central nervous system injury, lens displacement, hyphema, or globe disruption. Relative indications include subconjunctival ecchymosis and diminished ocular range of motion.

PALPATION

Touch lightly around the lips and cheeks to assess for diminished sensation from the trigeminal nerve, which is a sign of fracture. Palpate the entire scalp for signs of injury.

Bimanual palpation works best for examining the rest of the craniofacial skeleton. Palpate the bony prominences of the zygomas, zygomatic arches, and orbital rims and assess

them for tenderness, asymmetries, step-offs, or crepitus. Simultaneously palpating both sides allows comparison and makes detection of injury more likely. Assess mandibular integrity with bimanual manipulation while closely observing the teeth for movement, a sign of fracture. Newly missing teeth should be noted, along with the possibility that they may be in the airway [see Figure 4].

Gently palpate the nose for asymmetry, tenderness, or crepitus. Significant nasal fractures will often present with gross deformity visible on inspection alone [see Figure 5].

The maxilla should be evaluated for mobility relative to the skull base, an indication of the Le Fort fracture, discussed below. This is usually done by placing one hand on the forehead or bridge of the nose for stability and the other inside the mouth to grasp and mobilize the maxilla. If a Le Fort-type injury exists, the maxilla will move independent of the stable skull base.

Lastly, if the patient is able to speak, perceived changes in the quality of voice are indicative of laryngeal or cranial nerve X or XII injury. The presence of ecchymosis over the larynx or subcutaneous air in the anterior neck is an indication of significant laryngeal injury. In this situation, due consideration should be given before attempting intubation, which may turn a partial laryngeal or tracheal separation into a complete disruption. Fiberoptic intubation in a controlled surgical setting or proper surgical airway should be pursued if the suspicion of significant laryngeal trauma exists.

IMAGING

The facial skeleton is complex; it has varying degrees of osseous thickness and a large amount of three-dimensional (3D) complexity. The accurate diagnosis of fractures in the deeper areas of the midface, such as the orbit and frontal sinus, is not possible without computed tomography (CT).

Plain Radiography

Because of the complex anatomy of the face and its inability to image discrete areas, plain radiography of facial trauma is no longer useful, with one exception: the orthopantomogram (OPG), otherwise known as the panoramic radiograph

Figure 4 **Infraorbital fracture.**

Figure 5 **Broken nose.**

of the upper and lower jaw. Where available, the OPG is useful for diagnosis and treatment planning of mandibular and dentoalveolar fractures.

Computed Tomography and Magnetic Resonance Imaging

Overall, CT is the gold standard imaging modality for maxillofacial trauma. It has a range of sensitivity to visualize subtle injuries to thin bones and orbital soft tissues. CT allows volumetric (3D) rendering of the entire skull and mandible, which can be used for patient-specific 3D treatment planning and implant development. However, many maxillofacial injuries are visible only in standard axial, coronal, and sagittal cross-sectional format. 3D maxillofacial CT can simplify conceptual understanding of the injury, but cross-sectional windows should always be assessed.¹⁶ Outside its use for vascular imaging, magnetic resonance imaging is not often used in the evaluation of maxillofacial trauma.

CT angiography and magnetic resonance angiography are effective techniques to evaluate vascular injuries associated with maxillofacial trauma. Published regimens to manage vascular maxillofacial injuries are evolving toward selective surgical intervention based on combined clinical examination and angiography findings.¹⁷

Treatment of Soft Tissue Injuries

BASIC CONCEPTS

Maxillofacial soft tissue injuries are very common. They are the result of blunt or penetrating trauma and can involve finely detailed structures such as the facial nerve, parotid duct, or lacrimal drainage system. During initial examination,

signs of injury to these structures are an indication for specialist consultation.

All wounds should be thoroughly inspected for the presence of foreign bodies or broken teeth before irrigation, cleansing, and débridement. Irrigation with normal saline is usually adequate. If other agents are added, they should not pose any danger if they get into the eye. If the presence of deeper foreign bodies is suspected, plain radiography can be used to localize them before closure. After automobile accidents, broken glass, which is often radiolucent, may be found in the wound. Failure to adequately remove all loose fragments and foreign material can result in persistent local inflammation and residual cosmetic deformities.

Because of rich facial blood flow, even dusky tissues on small pedicles will often survive and may prove to be useful later on; conservative débridement of injured facial soft tissues is usually recommended.

To enhance hemostasis, an epinephrine-containing local anesthetic should be locally infiltrated for repair, except in areas of significantly compromised blood flow. Where possible, regional nerve blocks should be used because they will not distort the wound margins, which is preferable in areas such as the eyebrows, forehead, and lips, where specific tissue alignment is required. The infraorbital nerve, for example, can be blocked to provide anesthesia to the upper lip, side of the nose, and nearby soft tissues. Supraorbital nerve and mental nerve regional blocks are also useful.

Many soft tissue injuries of the face and scalp can be repaired with local anesthesia and standard layered closure in the emergency department, with good results. However, non-cooperative children and adults or patients with extensive or complex soft tissue injuries should be treated in the operating room under general anesthesia. If associated bony injuries will require future repair, then temporary closure of soft tissue injuries is sufficient. Lacerations are frequently used for access to underlying bony injuries, so definitive repair should be done after bony reconstruction.

Facial lacerations are usually closed in layers. Subcutaneous sutures should be placed to remove dead space and reapproximate the skin surface without tension. The purpose of skin surface sutures is not to pull open skin margins together but to gently reapproximate them. Tight skin sutures that strangulate the wound margins should be avoided. Always consider resorbable skin sutures in small children; the safe removal of these sutures can be very challenging in the uncooperative child.

Routine antibiotic use for simple nonbite facial soft tissue injuries is not indicated. When careful wound preparation is performed before repair, simple lacerations do not appear to benefit from prophylactic antibiotic therapy.^{18,19} A home care regimen of daily wound cleansing and coverage with a topical antibiotic ointment will usually suffice.

In more complex and grossly contaminated wounds, antibiotic coverage should be considered. Patients should be reminded to use sunblock with a sun protection factor of 15 or more on facial wounds for several months after initial healing to minimize darkening of the wound margins.

FACIAL AND TRIGEMINAL NERVE INJURIES

Injuries to the proximal facial nerve result in obvious and serious functional disabilities. When evaluating soft tissue

injuries around the facial nerve, its function must be assessed and documented before giving any local anesthetic. Evaluate the temporal branch by asking the patient to lift the eyebrows, the zygomatic branch by tightly closing the eyes, the buccal branch by smiling, and the marginal mandibular branch by pursing the lips or frowning. If the patient is unconscious, a nerve stimulator can be used to grossly assess the integrity of the facial nerve.

When evaluating the facial nerve, imagine a vertical line extending superiorly and inferiorly from the lateral canthus of the eye [see Figure 6]. Nerve injuries posterior to this line can be considered for nerve repair. Injuries to the nerve anterior to this line are generally too small to repair and will have adequate contralateral crossover innervation.

Patients with deep penetrating soft tissue injuries that involve the parotid gland, especially the deep posterior parotid gland, should be assumed to have a facial nerve injury until proven otherwise. Clean, sharp divisions of one of the proximal nerve branches should be identified and repaired with direct neurorrhaphy as soon as possible. If a defect in the nerve trunk of several millimeters or more exists, the ends of the nerve should be tagged for later repair by grafting.

Sensory nerve injury usually involves the trigeminal nerve; results in hypoesthesia or anesthesia of the facial brow, nose, lids, lips, and skin; and is a sign of associated bony injury. Altered sensation in these areas is often temporary; even when it is permanent, long-term disability from sensory nerve injury is usually minimal.

PAROTID DUCT INJURIES

The parotid duct extends anteriorly 2 to 3 cm from the anterior parotid gland and drains saliva into the mouth

Figure 6 Soft tissue injuries involving the facial nerve distal to the vertical line are likely too small for primary repair.

through an orifice found on the buccal mucosa just opposite the maxillary molars. Deep lacerations between the anterior parotid gland and this orifice can potentially damage the parotid duct.

If a ductal injury is suspected, a slender and flexible probe can be inserted retrograde through the duct orifice and back toward the parotid gland; if the probe is found protruding into the wound, then the duct has most likely been severed. If both ends of the severed duct can be located, then careful anastomosis over a stent or catheter can be performed to maintain duct continuity [see Figure 7]. Some studies demonstrate that normal wound closure without specific duct repair provides similar outcomes and that specific repair of the duct may not be necessary.²⁰

SCALP INJURIES

Shaving the scalp is not routinely necessary for laceration repair. The blood supply in this area is rich, and infection is very uncommon. When using cautery for hemostasis, remember that bleeding scalp vessels are deep to the hair follicles, at the level of the galea. Avoid excessive cautery in the superficial layers, which can lead to alopecia. Scalp lacerations are repaired in one or, at most, two layers.

Scalp injuries can create significant potential space between the scalp and the skull, allowing hematoma accumulation, so drain placement or head wrap may be necessary. Never use an active drain over a skull fracture. Primary repair of partial scalp avulsion will require extensive releasing incisions and local flap rotation; some can be left to granulate secondarily.

EYELID INJURIES

Laceration of the eyelid region should raise suspicion for penetrating ocular injury, which can exist with no external signs. Globe rupture or retained intraorbital foreign bodies may be present with only very small external signs of injury. Eyelid injuries come in two main types: those that involve the margin of the lid and those that do not. The former are more complex, and their repair is the domain of the subspecialist. Repair of lid margin injuries requires meticulous three-layer closure and close postoperative monitoring. Injuries that do not involve the lid margin should still be carefully examined and then closed in layers.

Mobilizing nearby soft tissue to repair areas of eyelid avulsion is difficult, and soft tissue débridement around the eyelids should be kept to a minimum, even if the tissue appears poorly perfused.

LACRIMAL DUCT INJURIES

Lacerations involving the medial quarter of the eyelids should be assumed to compromise the lacrimal drainage system. Repair of the ducts is highly specialized and involves microscopic identification and repair over a flexible stent. Identification of these ducts can be tedious; inaccurate probing in search of them will only further damage the drainage system, leading to epiphora (poor drainage and pooling of tears) later. Successful repair usually requires specialist consultation.

EYEBROW INJURIES

The eyebrows should never be shaved; they are required for accurate alignment of the tissue margins and usually will

Figure 7 Injuries to the parotid duct are repaired by passing a catheter through the Stensen duct and through the area of laceration and then repairing the parotid duct over the catheter.

not grow back. If débridement is necessary, incisions should be made parallel to the eyebrow hair follicles, which run obliquely under the skin surface. Doing so will minimize eyebrow alopecia, which is quite noticeable if it occurs.

EXTERNAL EAR INJURIES

Because of their prominence, external ear injuries are common. The ear is highly vascular, and circulation is often maintained, even in cases of partial avulsion when only a small pedicle is present.

Full-thickness auricle lacerations should be aligned and repaired in layers, but suturing of the cartilage layer is not always necessary. If total avulsion occurs, the cartilage should be deepithelialized and buried in a retroauricular subcutaneous pocket for use in later reconstruction.

Shearing of the vascular mucoperichondrium from the underlying cartilage can lead to hematoma formation. To maintain normal skin-cartilage contour and prevent cauliflower ear, these hematomas should be evacuated early followed by placement of a conforming pressure dressing on both sides of the auricle.

NASAL INJURIES

Soft tissue injuries of the nose create cosmetic concerns, but malalignment of injured supporting cartilage can also create functional problems. Mucosa should be repaired first, with resorbable suture; then both cartilage and skin should be repaired with fine nonresorbable suture. Structures with linearity (like the alar rim) or transition points (such as the skin-mucosa junction) should be carefully aligned or noticeable deformity will result.

LIP INJURIES

When repairing lip injuries, identification and alignment of the vermilion border on both sides of the laceration are critical. Direct infiltration of epinephrine or local anesthesia into the wound margins will make identification of the vermilion much more difficult. If direct injection is necessary, tattoo or mark the vermilion first. Through-and-through lip lacerations should be closed in layers. A key point is identification and direct suturing of the orbicularis oris layer, which reconstructs the oral sphincter and prevents notching at the lip margin. If ragged wound margins exist, sharp wedge excision will allow direct, well-aligned closure and a better cosmetic result. If dental injuries exist, lip lacerations should be examined for embedded tooth fragments.

Treatment of Maxillofacial Fractures

BASIC CONCEPTS

Maxillofacial fracture treatment paradigms differ from those of the axial skeleton. There are two windows for optimum treatment of maxillofacial injuries. The first 6 to 12 hours following injury, before the onset of edema, is typically reserved for urgent comorbidities (e.g., optic nerve compression, uncontrollable facial bleeding, pediatric trapdoor orbital fractures). In the multisystem trauma victim, this early treatment phase may not be possible because of the higher priority of other injuries. The most common timing for repair is 3 to 7 days postinjury, after the initial edema has subsided and the

patient is cleared for the operating room. If complicating injuries do not exist, most bony facial repair is done on an outpatient basis. Blood supply in the face is relatively rich, so, generally speaking, infection is less common and antibiotics are less necessary than when treating extremity fractures, even when repair is delayed.

The most common maxillofacial fractures are nasal, mandibular, orbital, and zygomaticomaxillary complex fractures. The paranasal sinuses (maxillary, ethmoid, frontal) are frequently involved. Surgeons with maxillofacial trauma expertise exist in the specialties of oral and maxillofacial surgery, otolaryngology, and plastic and reconstructive surgery. A multidisciplinary approach is frequently required, especially for complicated repair, with involvement of neurosurgery and ophthalmology.

PRINCIPLES OF MAXILLOFACIAL FRACTURE REPAIR

Successful surgical repair of facial fractures requires adequate exposure and visualization, mobilization and reduction, and stable internal fixation of the fractured segments, especially along the facial buttresses.¹⁶ Facial buttresses meet the following critical criteria: (a) they are all linked either directly or through another buttress to the cranium or cranial base as a stable reference point; (b) they have sufficient bone thickness to accommodate metal screw fixation; and (c) they are accessible through standard limited surgical incisions. Examples of vertical buttresses include the thickened bone that runs from the alveolus up the side of the nose to the frontal bone. An example of a horizontal buttress is the one that runs from the temporal bone, along the zygomatic arch and inferior orbital rim to the other side. Thin nonbuttress bone such as the anterior wall of the maxillary sinus does not require reduction and fixation.¹⁶

Accurate reduction and fixation of the facial buttresses restore projection, width, and height of the facial skeleton relative to the cranial base and, more importantly, establish functional support for the teeth and globes. Once this has been accomplished, the soft tissues of the face, such as the dissected periosteum, nasal cartilages, and ligamentous attachment of the eyelids, are resuspended in their correct position.

DENTOALVEOLAR INJURIES

Dentoalveolar trauma refers to isolated fracture or displacement of the teeth or its supporting bone, the alveolus. These injuries are very common, and the possibility of missing teeth or tooth fragments in the airway should be kept in mind.

Treatment usually involves reduction and splinting to nearby stable teeth. In some cases, extraction is necessary, but this is cosmetically devastating to the patient. Reconstruction of lost teeth and alveolar bone is expensive and time consuming, so efforts to stabilize and salvage existing teeth and bone are important.

MANDIBULAR FRACTURES

Gross mobility, malocclusion, and numbness of the lower lip are signs of mandibular fracture. Ecchymoses in the floor of the mouth or vestibule are also suggestive, and CT will confirm the diagnosis. Mandibular fracture alone is not usually an indication for emergent intubation. Even bilateral

mandibular fracture will not usually compromise the airway, except with severe displacement or in obtunded patients. Mandibular fractures are named by region, as in Figure 8.

Historically, all mandibular fractures were treated with several weeks of IMF and still are today in many places. However, open reduction and internal fixation (ORIF) offers more immediate mobility and, in many cases, the prospect of avoiding IMF altogether. Given that IMF inhibits respiratory function,²¹ avoiding it can be helpful for successful ventilator weaning.

Because it has teeth, complicated movement patterns, and relatively less vascularity, the mandible has a higher complication and infection rate than other facial fractures. Most infections are secondary to inadequate fragment stabilization or the presence of necrotic teeth and bone. In addition, the teeth fit in an extremely precise arrangement with the upper jaw, and failure to reestablish this relationship is often unacceptable to the patient.

Mandibular fractures are a result of the force sustained. Direct injury to the chin will fracture the symphysis along with the thin subcondylar area as the force is transmitted through the mandible. In any case, because the mandible is ring-shaped, the presence of one fracture should raise suspicion for a contralateral injury.

The goals of treatment are bony union and a normal occlusal relationship. Many simple fractures can be treated with closed techniques and limitation of function. More severe injuries requiring ORIF are approached and repaired through transoral or transcuteaneous incisions. The condylar fracture is the most controversial mandibular injury, largely because the facial nerve inhibits access to it. Because facial nerve injuries can be devastating, there is a bias toward closed treatment of the condyle, even when open treatment might be beneficial.

Mandibular fractures should be treated sooner rather than later, but many factors can lead to delayed treatment. In

general, open mandibular fractures should be treated within 2 to 3 days of injury, whereas closed fractures can be treated 7 to 10 days after injury if necessary.

MAXILLARY FRACTURES

The midface, like the front of a car, is designed to crumple in the presence of blunt force, absorbing energy and protecting the cranium and cervical spine. In 1901, Rene Le Fort performed a series of experiments on cadaver heads, demonstrating that blunt force fractures the midface along certain lines of inherent weakness: the Le Fort I, II, and III level fractures [see Figure 9 and Figure 10]. The Le Fort classification is universal and very helpful for communication and documentation, but Le Fort injuries can occur on multiple levels simultaneously and asymmetrically and in any combination. A fractured palate indicates significant energy transfer.

The lowest of these fractures, the Le Fort I, horizontally separates the palate and tooth-bearing maxilla from the rest of the midface. The Le Fort II, the so-called pyramidal fracture, includes the lower maxilla plus the medial infraorbital rim, orbital floor, and nasal bones [see Figure 9]. Le Fort III fractures, the craniofacial disjunction, pass through the upper portions of the orbits and include the zygomas; they are characterized by complete separation of the entire midface from the cranium [see Figure 10 and Figure 11].

Depending on the level of the Le Fort fracture, various incisions will be required. In general, higher-level fractures are more complicated and require additional access. The principles of treatment are the same, however: reestablish proper occlusion, line up the facial bony buttresses, and apply internal fixation at key structural points.

The midface is relatively vascular and immobile (unlike the mandible), so infection and nonunion are less common.

Figure 8 Mandibular fracture.

Figure 9 Le Fort I fractures (black line) affect the upper jaw alone. In Le Fort II fractures (red line), the upper jaw and the central portion of the face are separated from the skull.

Figure 10 In Le Fort III fractures, all of the facial bones are separated from the skull.

ZYGOMATIC FRACTURES

The zygoma forms the prominence of the cheek (the malar eminence) and a large part of the orbit. After nasal fractures, zygomatic fractures are the most common bony injury from blunt trauma. To prevent noticeable flattening of the face or impingement of mandibular opening, even minimal zygoma displacement can require repair [see Figure 12].

The degree of displacement and the difficulty of repair depend on the amount of energy absorbed. Simple low-energy injuries can often be treated by oral access alone, whereas high-energy injuries are fragmented at the margins, requiring both oral and orbital access with multiple-point fixation. Accurate alignment of the zygomatic fracture can be challenging because of the combination of rotary and translational displacement of the bone fragments.

It is important to remember that any injury severe enough to displace the zygoma and change the shape of the orbit has the potential for ocular injury or globe malposition. An ophthalmology consultation should be considered for every zygomatic fracture, especially when associated with other ocular findings. If the globe is injured, bony surgery may need to be postponed.

ORBITAL FRACTURES

Orbital injuries can occur in isolation or as a component of more extensive injuries. The main concern in orbital trauma should always be injury to the globe and visual loss. The orbit is lined with thin bone that fractures when blunt force meets the globe, as in an assault. The globe is prevented from

Figure 11 Findings in patients with Le Fort III maxillary fractures immediately after injury, before obliterative edema develops.

Figure 12 Preoperative (*left*) and postoperative (*right*) orbitozygomatic fracture on the patient's right side. Note the decreased width and projection of the zygoma position preoperation, which is a combination of rotation and translation deformity. Postoperation, anatomic reduction has been achieved, along with titanium plate fixation along the facial buttresses.

rupturing by fracture of this thin bone, instantly increasing the volume of the orbit. This traumatically acquired increase in orbital volume needs repair to prevent permanent posterior-inferior displacement of the eyeball within the distorted orbit (enophthalmos) and associated diplopia.²²

Orbital repair is achieved through a transconjunctival or periorbital transcutaneous approach and the restoration of normal orbital shape and volume with implants or bone grafting. Both zygoma and orbital fractures can be repaired any time within 2 to 3 weeks of injury.

The exception to this timing is pediatric trapdoor fractures.²³ Entrapment of the inferior rectus in children can easily be missed because the flexible bone can spring back into place like a trapdoor and look normal on a CT scan, except for the entrapped muscle under the bone in the maxillary sinus. These children can often present to emergency departments with abdominal pain as a result of the visceral response from the muscle entrapment. If a vision check is not performed at the initial evaluation, the underlying injury can be missed as the abdominal pain is worked up. This trapdoor fracture requires urgent treatment within 24 to 72 hours to minimize the chance of motility problems.

NASAL FRACTURES

Nasal fractures are the most common type of maxillofacial fracture. The vast majority of isolated nasal fractures can be treated with good results by simple closed reduction within 2 to 3 weeks of injury. This is accomplished with a blunt

instrument placed inside the nose, under the nasal bones, combined with external digital forces as required to realign the fractured segments. Internal nasal packing or external splinting is sometimes required. If these simple techniques do not achieve an acceptable result, a proper rhinoplasty may be required after a period of initial healing.

NOE FRACTURES

A significant NOE injury is devastating to the appearance and difficult to repair; in this region, even small discrepancies can significantly alter a patient's appearance. The thin bone of the NOE region provides nasal projection and a point of attachment for the medial canthi of the eyelids. When significantly injured, nasal projection is lost, and the distance between the medial canthi widens (telecanthus). Repair is challenging because of the number of thin, specialized structures and difficult access. Unless bony architecture and normal intercanthal distance are reestablished, the patient will have a permanent deformity that cannot be disguised.^{24,25} If CSF rhinorrhea is present, a neurosurgical consultation should be obtained. Injuries to the dura in the anterior cranial fossa can result in persistent CSF leakage and can be difficult to repair. In certain cases, transnasal endoscopic repair is possible.²⁶ By definition, the ethmoid sinus and walls are damaged in NOE fractures. If there is bilateral injury in this region, the nasofrontal ducts that drain the frontal sinus are also likely disrupted. This disruption of frontal sinus outflow can require obliteration of the frontal sinus. Failure

to diagnose and treat severe disruption and obstruction of the nasofrontal ducts increases the risk of the patient developing delayed complications, such as frontal sinus mucocele.

FRONTAL SINUS FRACTURES

Fractures of the frontal sinus are signs of significant cranial energy transfer. Isolated anterior table fractures with significant displacement will require repair to prevent a visible frontal deformity. Combined anterior-posterior table fractures with significant posterior table displacement disrupt the barrier that normally separates the brain from the aerodigestive tract. Injuries to the frontal sinus can also compromise the sinus outflow tract, as mentioned above.²⁷ Injuries to the frontal sinus area often require a combined CMF-neurosurgical approach. The goal of frontal sinus treatment is to create a “safe sinus,” one that drains into the nose and does not communicate with the brain. If this is not possible, the sinus may be removed entirely, performing a procedure called cranialization, which involves removing the posterior

wall of the sinus and separating its remnants from the cranium. Additionally, the frontal sinus can be “obliterated” by blocking the drainage ducts and filling the sinus with material such as bone or fat. Patients with posterior table injuries require long-term follow-up care because potentially life-threatening complications, such as meningitis or mucocele, may develop long after the original injury.²⁸

Summary

Facial trauma should be considered an indicator of associated critical injuries. The initial evaluation needs to include consideration of airway management, cervical spine injury, visual assessment, control of bleeding, identification of CSF leaks, and neurologic injury. The definitive diagnosis of maxillofacial injuries follows a structured history and physical examination and close evaluation of CT imaging.

4 INJURIES TO THE NECK

David H. Wisner, MD, FACS, and Joseph M. Galante, MD*

Assessment and Management of Neck Injuries

Injuries to the neck can be the result of blunt and penetrating trauma. Both mechanisms can cause devastating injuries, with high associated morbidity and mortality rates. Although penetrating neck trauma can be dramatic, blunt injuries may present in a more subtle or delayed manner, such as blunt cerebrovascular injuries, that create a diagnostic challenge. Having an understanding of anatomy and potential injuries can assist in developing a simple systematic approach to patients with injuries to the neck. Airway management in trauma does not differ based on the mechanism of injury. The principles that dictate airway management are universal; unfortunately, the management of blunt and penetrating injuries is not. After discussing airway management, the management of these patients will be separated into penetrating and blunt mechanisms to accommodate the unique considerations specific to each of these different mechanisms.

Airway

INITIAL MANAGEMENT

The initial priority, as with all trauma patients, should be to ensure an adequate airway.¹ Assessment of the airway can be done easily by talking to the patient. **Attention should be paid to signs of an injury, for example, dysphonia, stridor, or gurgling. In these patients, orotracheal intubation is required.** During intubation, blood and edema in the airway should be noted. In more extreme cases, a surgical airway may be needed by means of either cricothyrotomy (in emergency cases) or tracheotomy (in less extreme cases). Nasotracheal intubation is not advisable in the majority of trauma settings.

Patients with major airway injuries (i.e., penetrating laryngeal injuries) who are awake will position themselves to best protect their airway. They may want to sit upright and lean forward to keep their airway patent and allow for drainage of blood and secretions. In these patients, one may forgo cervical and spinal precautions to maintain an airway. Attempts to reposition them should be avoided until a definitive airway

can safely be accomplished, even if it means going to the operating room.

Cricothyrotomy

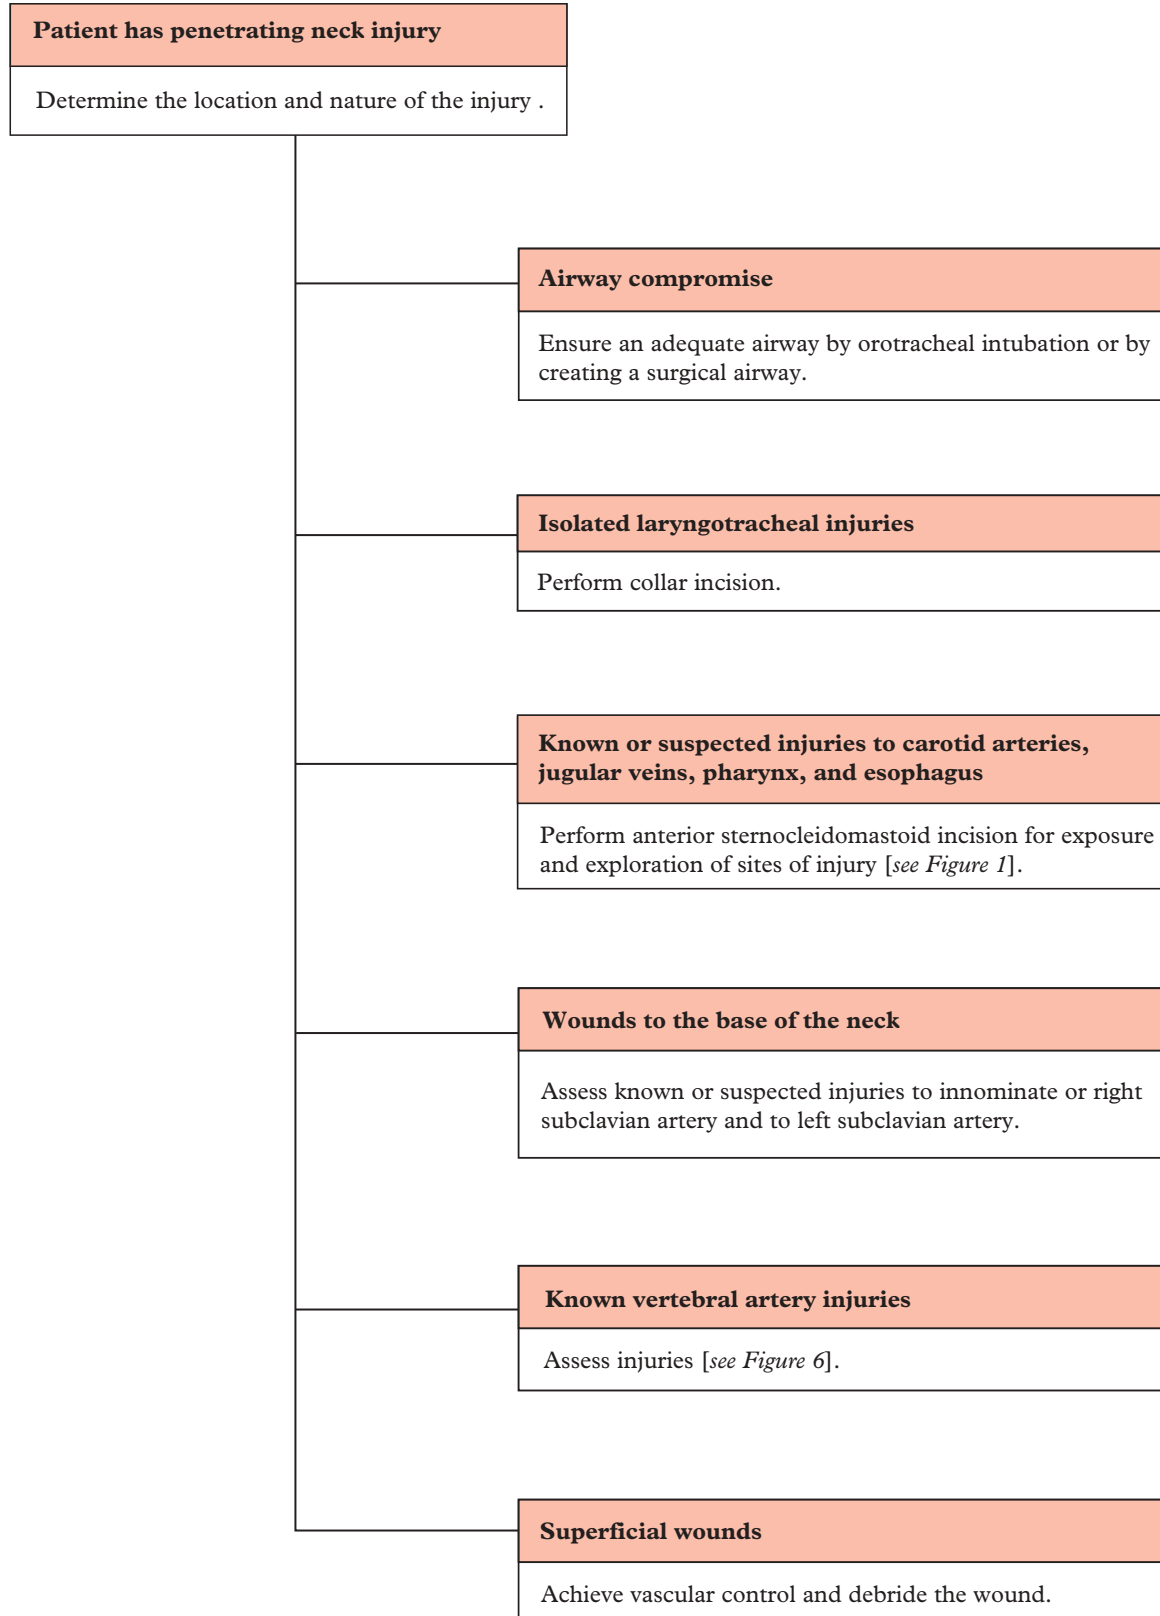

In emergency situations, when oral intubation is not successful or feasible, a cricothyrotomy should be done. The landmarks of the superior (notched) and inferior borders of the thyroid and the cricoid cartilage should be palpated. It is helpful to stand on the patient's right side (for a right-handed surgeon) and to stabilize the cartilaginous framework by holding the thyroid cartilage in place with the left hand. A transverse incision should be made at the level of the cricothyroid membrane and developed rapidly through the subcutaneous tissue. As with any transversely oriented incision of the anterior neck, the anterior jugular veins are at risk for injury. A vertical incision should be used if there is a suspected injury to the trachea but the exact location is unknown. This incision allows access to as much of the anterior surface of the airway as possible and improves visualization by decreasing the chance of injury to the anterior jugular veins.

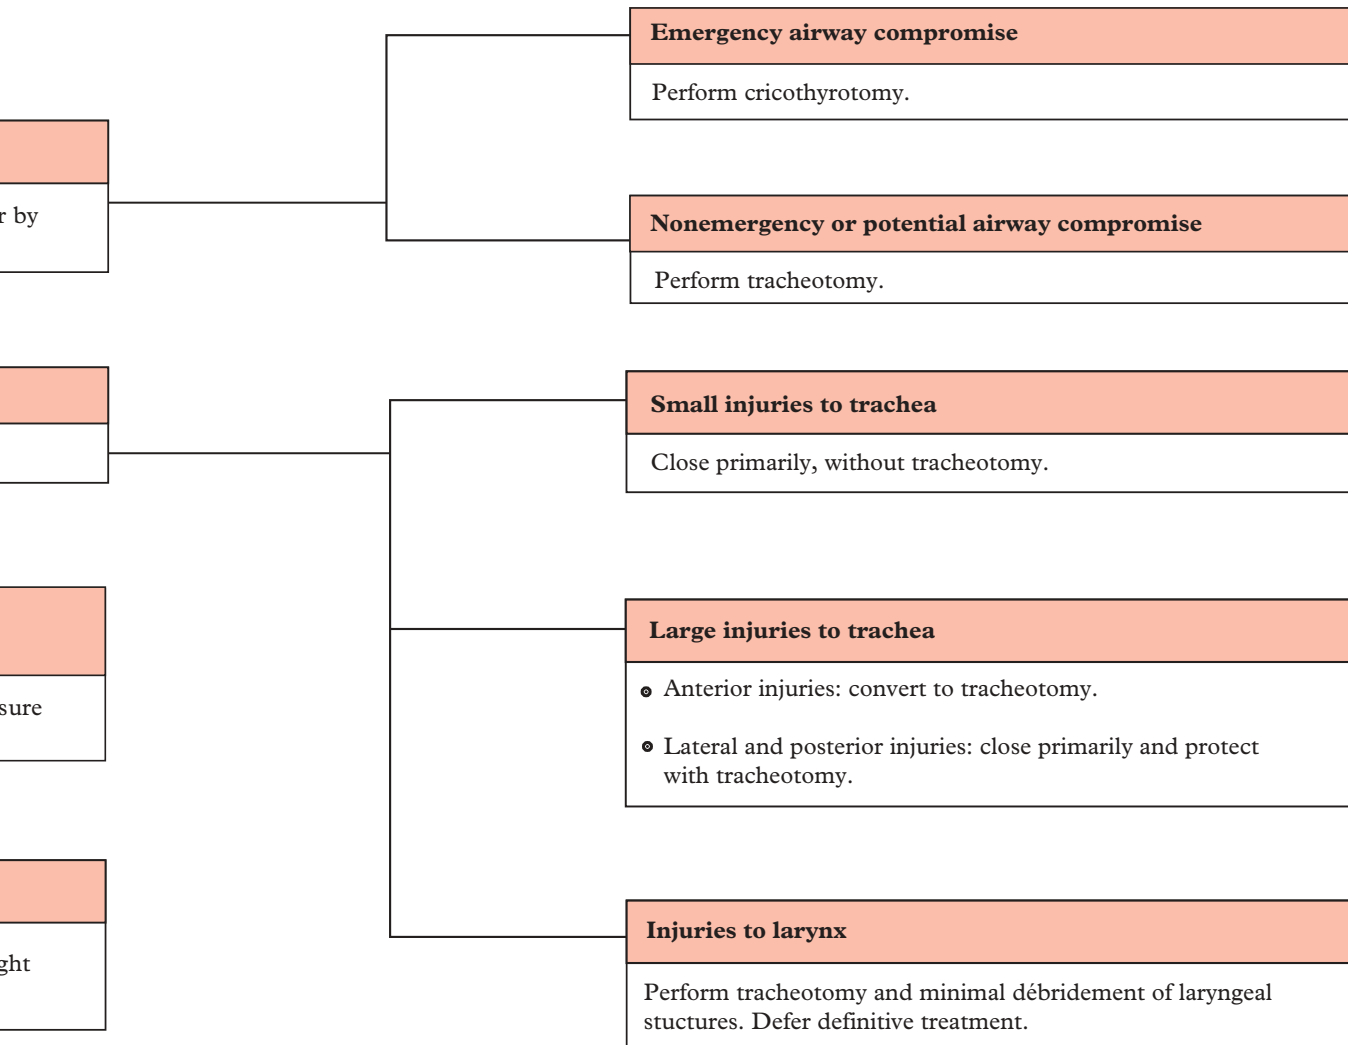

After the skin and the subcutaneous tissue have been divided, an incision should be made through the cricothyroid membrane. This is most rapidly done with a No. 11 knife blade. It is important to avoid pushing the knife blade too far and causing injury to the posterior wall of the airway or to the posteriorly located hypopharynx and esophagus. After the incision has been made, it can be enlarged by using a tracheotomy hook on the thyroid cartilage or by placing the knife handle in the incision and twisting it 90°. At this point, an indwelling definitive airway should be placed and secured. In most adults, a No. 4 or larger endotracheal tube or tracheotomy tube is adequate for initial placement. Any incisional bleeding from veins or other vessels should be controlled at this time; bleeding during the initial portion of the procedure should not distract from an appropriate focus on first establishing the airway. As with all procedures, and in particular with cricothyroidotomy, a face shield is imperative for the providers' protection from blood or secretions coughed out on entering the airway.

Controversy exists over the conversion of emergency cricothyrotomies to tracheotomies. The traditional view, initially promulgated by Chevalier Jackson in 1921, is that cricothyrotomy is more likely than tracheotomy to result in airway stricture or damage to more proximal structures in the larynx.² On the basis of this rationale, cricothyrotomies were converted to tracheotomies on a semielective basis within 24 to 48 hours of admission if the patient's general condition permitted.^{3,4} This practice continued until Brantigan and Grow published an article in 1976 showing a low complication rate

* The authors and editors gratefully acknowledge the contributions of the previous author, Robert C. Jacoby, MD, FACS, to the development and writing of this chapter.

Assessment and Management of Neck Injuries

with elective cricothyroidotomies.⁵ Recent studies in trauma patients show that there is a higher rate of complications in patients who had their cricothyroidotomy converted rather than left as a cricothyroidotomy.⁵ Some have even advocated that elective cricothyroidotomies may be used preferentially in critically ill patients with difficult neck anatomy because of the low complication rates.⁶ In patients with median sternotomies, the higher placed cricothyroidotomy is preferred to avoid secretions at the incision site. Although more data are becoming available showing similar or improved outcomes with cricothyroidotomy, it is still typical to convert a cricothyroidotomy to a tracheostomy in 1 to 2 days in a stable patient.

Tracheotomy

In some instances, airway compromise may not be extreme but a surgical airway may still be necessary for safety or subsequent management (i.e., laryngeal injury). In such circumstances, a tracheotomy rather than a cricothyrotomy should be done because cricothyrotomy may make definitive treatment more difficult.

The initial approach for urgent tracheotomy is similar to that for tracheotomy, the difference being that a so-called collar incision is made at a point two fingerbreadths inferior to the level of the cricothyroid membrane rather than above the sternal notch. The incision should be wide enough to provide rapid exposure and should extend as far as the anterior border of the sternocleidomastoid bilaterally. Anteriorly located injuries at the level of the cricoid or the trachea may already have created a hole in the airway. In such cases, if the need for a surgical airway is immediate, the wound should be enlarged and used as a route of access to the airway.

Penetrating Neck Trauma

INITIAL MANAGEMENT

Once an airway has been established, patients with penetrating trauma need to be evaluated in accordance with Advanced Trauma Life Support (ATLS) guidelines.⁷ Management of penetrating neck trauma starts by determining the depth of the wound. If the wound did not violate the platysma, injury to major underlying structures can be ruled out. If the wound clearly violated the platysma or its depth cannot be determined, further investigation is warranted. Patients with any obvious hard signs of vascular injury⁸ (e.g., pulsatile bleeding from the wound, an expanding hematoma, a bruit, or a neurologic deficit), shock, or air bubbling from the wound require immediate operative exploration. If the patient is stable and has no obvious signs of underlying vascular injury, a nonoperative workup should be obtained regardless of the location of the skin wound [see Figure 1].

Historically, management of penetrating neck injuries included categorizing them on the basis of their location in the neck. In this schema, the neck was divided into three distinct zones [see Figure 2], and management was determined by the zone in which the patient happened to have wounds in the skin. Zone I was from the clavicles to the inferior aspect of the cricothyroid cartilage and included the trachea, esophagus, aortic arch, great vessels (subclavian and carotid arteries as well as jugular veins), and cervical spine. Zone II, the largest of the three zones, extended from the inferior aspect of the cricothyroid cartilage to the angle of the mandible and included the aerodigestive tract, great vessels of the neck, and cervical spine. Zone III was from the angle of the mandible to the skull base and included the aerodigestive tract (the oral cavity, pharynx, and larynx), great vessels, cervical spine, and cranial vault.

The idea was that hemodynamically stable patients with zone II injuries presumably had underlying injuries to either the vasculature or the aerodigestive tract that were easily accessible via a sternocleidomastoid incision; such patients would therefore undergo mandatory neck exploration if the wound had violated the platysma. Zone I and III injuries, because of potential difficulties in obtaining proximal or distal control of the vessels through a standard incision,⁹ were worked up radiographically, and if no injury was identified, the patients were observed.

This concept of mandatory exploration of patients with zone II injuries and nonoperative workup of zones I and III has a number of problems. Division of the neck into three distinct areas results in extremely small zones I and III, and even zone II, in the middle of the neck, is not very long in most patients. As a result, determining that a given wound is clearly in only one of the zones is often very difficult. Description of a wound as being on the border of zones I and II or on the border of zones II and III is a common and confusing occurrence. Moreover, the location of the skin wound is not a reliable guide to the location of injuries to underlying structures. In penetrating trauma, the path of the missile or blade is clearly as important as the location of the skin wound. An object that enters the skin in zone II can easily injure structures in zone I or III, depending on the direction in which it entered the skin. A selective approach regardless of zone reduces the rate of negative neck explorations. Therefore, the zones of the neck are useful as descriptors but not as a guide for management.

Patients with wounds at the base of the neck should be identified early because of the high likelihood of an intrathoracic injury. A median sternotomy should be done for unstable patients with injuries at the base of the right neck or patients in whom the superior mediastinum is the most likely site of injury. Arterial injuries in such circumstances are usually to either the innominate artery or the right subclavian artery. Exposure of injuries to the proximal left subclavian artery is difficult via sternotomy because of the artery's posterior location; in patients with such injuries, a left thoracotomy is needed.

PENETRATING TRAUMA: STABLE PATIENT

Patients who do not require immediate operative intervention need a logical diagnostic approach to prevent missing an

Figure 1 Algorithm outlining operative management of known or suspected injuries to the carotid arteries, jugular veins, pharynx, and esophagus.

Figure 2 The traditional division of the neck into three separate zones. This division has been used as a basis for decision making with respect to penetrating cervical injuries.

injury. Evaluation modalities are needed for each of the structures of the neck, including vascular, aerodigestive, and bony structures. Computed tomography (CT) is used to evaluate the bony structures. With reconstruction technology, multidetector CT scanners can provide three-dimensional images of the cervical spine and facial bones.¹⁰

CT scanners are not as effective as screening tools for aerodigestive injuries. These structures, the larynx, pharynx, hypopharynx, cervical esophagus, and trachea, should be directly visualized. This evaluation may take many forms, including indirect laryngoscopy, flexible fiberoptic nasopharyngolaryngoscopy, flexible bronchoscopy, and rigid or flexible esophagoscopy.¹¹ Flexible endoscopy, although the preferred method for airway assessment,¹² may miss small injuries in redundant tissue when evaluating the hypopharynx and cervical esophagus.¹³ If the patient has a cleared cervical spine and there is an extremely high index of suspicion for

missed injury, rigid esophagoscopy should be done. If the cervical spine is not cleared and the patient can swallow contrast, esophagoscopy may be performed but does not provide visualization of the proximal oropharynx and hypopharynx. It is important to emphasize that injuries to the pharynx are much more common than those to the cervical esophagus and that such injuries are best diagnosed by laryngoscopy and pharyngoscopy rather than by esophagoscopy or esophageal contrast studies.

SCORE For vascular injuries, conventional angiography was for many years the gold standard for ruling out vascular injury, but it is invasive, can be time consuming, and is resource intensive. With the advent of multidetector CT scanners, CT angiography has sensitivities and specificities that approach those of conventional angiography.¹⁴ CT can be quite helpful in determining the course that a knife or bullet took within the neck. If CT defines a knife or bullet tract that is clearly remote from major vascular or aerodigestive structures, no further workup is needed. If CT clearly shows an injury that should be repaired, exploration of the neck is indicated. If CT can neither establish nor rule out the presence of a vascular or aerodigestive injury, further imaging should be performed.

SCORE Retained projectiles cause scatter or air in the tissue planes, which may disrupt the quality of the images, and alternative diagnostic modalities need to be used. The air may be from the projectile or from an aerodigestive tract injury, and further imaging or endoscopic studies should be done.^{15,16}

Carotid Artery Exploration and Repair

SCORE The operative approach requires access to all structures in the neck, especially if the exact location of injury is not known. This is best accomplished with an incision along the anterior border of the sternocleidomastoid muscle [see Figure 3]. The sternocleidomastoid incision has three advantages. First, it provides exposure of the carotid sheath, the pharynx, and the cervical esophagus. Second, it can be lengthened to provide more extensive proximal or distal exposure. Finally, if bilateral exploration is necessary, separate sternocleidomastoid incisions can be done.

The patient is placed in the supine position, with the head turned away from the side of exploration and the neck extended. In this regard, it is helpful to clear the cervical spine before operation if possible. If both sides of the neck are to be explored, the head is left in the midposition, facing up. The entire neck and the appropriate side of the face and head are prepared. The anterior chest is also included in the preparation in case a median sternotomy is necessary for proximal control. The patient is draped so that the lateral neck is left as the primary field while the chest is kept easily accessible. The lateral chin and the tip of the earlobe are also kept in the field to provide landmarks. If the possibility exists that the injury is to the distal subclavian artery or the axillary artery, the patient's arm should be draped in a way that allows it to be manipulated.

The skin incision is carried through the dermis and the platysma. After the platysma is divided in the direction of the incision, the investing fascia overlying the anterior border of

Figure 3 In general, exposure of structures in the anterior areas of the neck is best done through an incision oriented along the anterior border of the sternocleidomastoid muscle.

the sternocleidomastoid muscle is incised, and the muscle is retracted laterally and posteriorly to expose the carotid sheath. It is often necessary to divide a venous branch that connects the external jugular vein posterolaterally to the anterior jugular vein anteromedially. This vein lies in a plane immediately deep to the platysma.

Classic principles of vascular surgery apply; proximal and distal control should be obtained before exploration of a carotid artery injury. Obtaining proximal control before entering a perivascular hematoma is more important than having distal control, and if necessary, distal bleeding can be controlled with digital pressure while the dissection of the injured vessel is completed. Although it is often difficult to obtain control before addressing the area of injury, proximal and distal control of the vessel should be obtained at some point before any attempts at definitive repair. For injuries near the carotid bifurcation, it is necessary to control the common, internal, and external carotid arteries, as well as the proximal branches of the external carotid artery. This should be done with vessel loops; ligation of vessels should be avoided.

The initial exploration should attempt to rule out arterial or venous injury unless an overt airway injury is present and requires immediate attention. The location of the carotid artery can be confirmed by the presence of a pulse. **SCORE** The carotid sheath contains the jugular vein, carotid artery, and vagus nerve. During dissection of the carotid sheath and retraction of the jugular vein, care must be taken to keep from injuring the associated vagus nerve. Division of the facial vein, which is superficial to the carotid bifurcation, facilitates jugular vein retraction. The severed ends of the facial vein should be suture-ligated to ensure that the ties will not come

off with increased intravenous pressure in the postoperative period—for example, secondary to a cough or a Valsalva maneuver [see Figure 4].

Exposure of the proximal common carotid artery at the base of the neck is easier after division of the omohyoid muscle at the point where its superior and inferior bellies are joined. Division of the omohyoid muscle results in minimal functional deficit postoperatively. For proximal control of the common carotid artery, it may be necessary to enter the chest via median sternotomy. To minimize blood loss, the decision to do a sternotomy should be made without undue delay. Control of the proximal right common carotid artery via this route is relatively easy and is accomplished by dissecting distally along the innominate artery. Proximal control of the left common carotid artery via median sternotomy is more difficult because its origin from the aortic arch is more posterior than the origin of the innominate artery. Left thoracotomy should be done when the proximal left internal carotid artery is injured, especially if the patient is in extremis. If a proximal left common carotid injury (or proximal left subclavian artery injury) is known or suspected preoperatively, it is helpful to bump up the patient's left hip and shoulder to position the left chest 20° to 30° anteriorly. The head is turned to the right, and the left arm is prepared as far as the elbow and draped to allow it free movement. Moving the arm is helpful when proximal exposure and control are obtained through the chest and distal exposure and control are obtained through a supraclavicular incision. Moving also allows improved exposure of the axillary artery if necessary.

If a median sternotomy has been done for exposure of an innominate artery or right subclavian artery injury, it may prove necessary to extend the incision into the right neck to obtain adequate distal control and exposure. Either a right supraclavicular or an anterior sternocleidomastoid extension can be used. Although both are easily accomplished, the anterior sternocleidomastoid extension is the more versatile of the two.

Figure 4 After a plane along the anterior border of the sternocleidomastoid muscle has been developed, dissection is carried down to the level of the carotid sheath. Suture ligation of the facial vein facilitates this dissection. Lateral retraction of the internal jugular vein improves exposure of the carotid bifurcation.

For wounds to the distal internal carotid artery, exposure can be difficult. A 3 to 5 French Fogarty balloon catheter can be placed through the area of injury or through a proximal arteriotomy to help with distal control. The catheter should be advanced distally and the balloon inflated to provide a dry field for arterial repair. Repair can be done around the catheter; the balloon is deflated near the conclusion of the repair, and the catheter is removed before the final several sutures are tied.

If exposure of the distal internal carotid artery is needed, a number of important structures should be identified and protected [see Figure 5]. The hypoglossal nerve is usually encountered within several centimeters of the carotid bifurcation and should be dissected free of the internal carotid and retracted upward. This is facilitated by division of the occipital artery, which crosses superficial to the hypoglossal nerve on its course from the external carotid artery toward the occiput. It is also helpful to divide the ansa cervicalis branches that run inferiorly from the hypoglossal nerve to supply the muscles of the neck. Injury to the hypoglossal nerve results in impaired motor function of the tongue and can lead to dysarthria and dysphasia. Injury to or sectioning of the ansa cervicalis causes little or no morbidity.

Further distal exposure of the internal carotid artery may require unilateral mandibular subluxation or division of the ascending ramus of the mandible.⁴ Such maneuvers are somewhat easier when the patient is nasotracheally intubated. They increase the size of the small area immediately behind the condyle and allow easier division of the stylohyoid ligament and the styloglossus and stylopharyngeus muscles. These three structures can be divided together adjacent to their common origin at the styloid process. If this is done, care should be taken to preserve the facial nerve, which lies superficial to these muscles and must be dissected free of the muscles before they are divided. The underlying glossopharyngeal nerve, which lies deep to these muscles and superficial to the internal carotid artery, should also be protected by dissecting it free of the muscles before their division. Injury to the facial nerve results in loss of function of the muscles of facial expression. If the glossopharyngeal nerve is injured, loss of motor and sensory supply to parts of the tongue and pharynx increases the risk of aspiration.

Once the muscles originating from the styloid process have been divided, the styloid process itself can be resected to gain a further short distance of distal exposure. In very rare instances, it may prove useful to remove portions of the mastoid bone to provide even more distal exposure of the internal carotid artery as it enters the carotid canal. For more distal lesions, it is necessary to place a posterolateral scalp incision, reflect a medially based scalp flap, and divide the ipsilateral external auditory canal. This approach results in better exposure of the mastoid process and allows exposure of the intrapetrous portion of the internal carotid after removal of the overlying bone of the mastoid with a high-speed bone drill.

During dissection of the external carotid artery, the branches should be identified. They can be ligated if necessary but should be preserved if possible (this usually depends on whether they can be temporarily occluded with vessel loops, a looped suture, or clips). During dissection around the common and internal carotid arteries, care should be taken to avoid cutting or clamping the posterolaterally located vagus nerve; the recurrent laryngeal nerve runs with the vagus nerve at this level, and damage to the laryngeal nerve can lead to paralysis of the ipsilateral vocal cord.

Figure 5 During distal dissection of the internal and external carotid arteries, a number of important structures are encountered, including the hypoglossal nerve and the occipital artery.

If associated injuries allow, a 5,000- to 10,000-unit bolus of heparin should be given before any of the arteries in the neck are occluded. Because they have no branches, the common and internal carotid arteries can be safely mobilized for some distance from the injury to ensure a tension-free repair.

Management of common or external carotid artery injuries is governed by the extent of injury and the overall status of the patient. Simple injuries to the external carotid artery should be repaired, whereas complex injuries should be ligated given that the external carotid artery normally has such good collateral flow. Even in cases with complex injuries to the common carotid artery, if the patient has no neurologic deficits, ligation can be done. The internal carotid will be reconstituted with flow from the external carotids.

Injuries to the internal carotid artery are more problematic. If the injury is simple and there is no suggestion that flow in the vessel has been interrupted, repair should always be undertaken. An example of such an injury is a simple stab wound of part of the circumference of the artery with an associated pseudoaneurysm and good distal flow. In this circumstance, lateral repair can be done quickly and easily with a short cross-clamp time.

After proximal and distal control of the vessel is obtained, a check should be made for back-bleeding. If the back-bleeding from the distal circulation is brisk, as it usually is, repair can be done safely.

If an injury to the common carotid artery or the internal carotid artery has interrupted flow in the vessel, repair creates a theoretical disadvantage. Interruption of flow may lead to focal brain ischemia and partial disruption of the blood-brain barrier. Sudden restoration of blood flow may cause hemorrhage in the area of the ischemia and worsen the extent of brain injury; an anemic, or white, infarct of the brain may be converted to a hemorrhagic, or red, infarct. Whether this pathophysiology is important after traumatic injury is unclear and controversial.

Deciding whether to repair or ligate when flow has been interrupted is often difficult. One approach is to base the decision on the patient's preoperative neurologic status. If there is no neurologic deficit, it is presumed that there are no areas of brain ischemia and that repair is safe. Conversely, a focal neurologic deficit is presumed to be related to ischemia, and in such cases, the risk of worsening the patient's neurologic status with restoration of blood flow is increased. Even though this approach

is rational, it is not applicable in cases in which a detailed neurologic examination before surgery is not possible. Furthermore, this approach may be applicable only to patients in coma or with severe neurologic deficits. There are indications that milder neurologic deficits respond favorably to revascularization.

Yet another approach is to gauge the appropriateness of repair according to the nature of the injury itself. In this approach, large, complicated injuries requiring involved and lengthy procedures for repair are ligated, whereas simple injuries requiring only simple and quick repairs are repaired. Similarly, repair is not indicated in patients with severe or multiple associated injuries. There is also a difference between the management of injuries of the common carotid artery and the management of injuries of the internal carotid artery. Common carotid injuries are more accessible and easier to repair, and repair is generally associated with a good outcome. Continued antegrade flow in the internal carotid artery is more likely after injury to the common carotid artery than after injury to the internal carotid artery because of the possibility of collateral flow via the external carotid artery.

A reasonable way to deal with repair dilemmas is to make the decision on the basis of distal back-bleeding. Interruption of blood flow to the brain is tolerated only for a short time, and restoration of flow is unlikely to be accomplished quickly enough to improve outcome. It is therefore logical to base the decision about revascularization on the state of back-bleeding from the internal carotid artery. If back-bleeding is brisk, the patient is presumed to have good collateral flow, and the chances that there is an area of ischemia are low. Repair rather than ligation is safe in such circumstances. If internal carotid artery back-bleeding is minimal or absent, an ischemic infarct is more likely and restitution of arterial inflow is more dangerous. A corollary to this reasoning is that if back-bleeding is poor, a clot distal to the area of injury may be present, and return of flow with repair may dislodge the clot distally.

If a carotid artery injury involves minimal loss of vascular wall, primary repair is straightforward and can be done with either a continuous or an interrupted technique; interrupted sutures will not purse-string the vessel. In younger patients who are still growing, interrupted sutures should be used to prevent later stenosis. As in elective vascular surgery, nonabsorbable sutures should be used; the carotid arteries generally require a 5-0, 6-0, or 7-0 monofilament suture, depending on the location of the injury and the type of suture material employed.

Defects longer than 1 to 2 cm should not be repaired primarily, because this will place excessive tension on the repair. For large defects limited to one surface of the vessel, a patch repair should be done. Either a venous patch or a synthetic patch can be used; when available, a venous patch is preferred for better long-term patency and to avoid placing a foreign body in a potentially contaminated wound. Saphenous vein from the groin is preferable for patches because of its durability; a saphenous vein from the ankle is easiest to harvest when time is of the essence. Although the jugular vein is in the operative field and can be easily harvested, it is better not to interfere with venous outflow in a neck in which the arterial inflow is to undergo repair; in addition, the jugular vein is very thin and difficult to handle.

For repairs near the carotid bifurcation, an alternative to venous patches and synthetic patches is the use of the proximal external carotid artery. This approach is especially appropriate

when the origin of the external carotid artery is itself involved in the area of injury. If the injury is to the proximal internal carotid artery and the origin of the external carotid artery is free of injury, it is better to leave the external carotid artery patent and to use a venous patch or a synthetic patch instead; if the repair fails, the external carotid artery provides collateral distribution to the internal carotid artery via the ophthalmic artery. An alternative approach is to transpose the proximal external carotid artery to replace the proximal internal carotid.

Repair of circumferential loss of the common or internal carotid arteries is difficult. In this circumstance, if the defect is too long for primary anastomosis and the patient's general and neurologic condition permits, an interposition graft is indicated. As with patch grafts, although either venous or synthetic material can be used, saphenous vein from the groin is generally the donor material of first choice because of its strength. The saphenous vein from the groin is also well suited for reconstruction of the common carotid artery.

Completion angiography should be done after interposition graft placements and complex repairs of the common or internal carotid arteries. In general, patients with carotid artery injuries should be admitted postoperatively to an intensive care unit (ICU). ICU observation need not be prolonged but should be continued for at least 12 to 24 hours postoperatively. In the early postoperative period, the patient should be observed for bleeding or for the development of a neck hematoma; large postoperative hematomas may compromise the airway. If a tense hematoma develops postoperatively, reexploration is mandatory. Acute changes in the neurologic examination are a potential sign of thrombosis or embolism from the site of injury and should prompt further investigation or reexploration.

Labile blood pressure—particularly in patients with extensive dissection around the carotid bifurcation—is another potential postoperative problem. It is related to manipulation of the carotid body, and control may require pharmacologic intervention. Labile blood pressure is usually self-limiting and disappears over the first 1 to 3 days after operation, but this is another reason why patients with carotid artery repairs should be monitored initially in the ICU.

Antibiotics should be administered preoperatively to cover common skin flora and should generally not be continued postoperatively unless there has been violation of the aerodigestive tract.

Vertebral Artery Exploration and Repair

In the rare case of a patient who presents with active, severe bleeding and in whom the most likely source of bleeding is the distal vertebral artery, surgical exposure of the vertebral artery is necessary. Initial exposure should be obtained via an anterior sternocleidomastoid incision. This approach can be used for exposure of both the proximal and the distal vertebral artery. The incision is developed down to the level

of the carotid sheath. The lateral margin of the internal jugular vein is developed sharply, and the internal jugular vein and the other contents of the sheath are retracted medially. After retraction of the carotid sheath, the plane just superficial to the

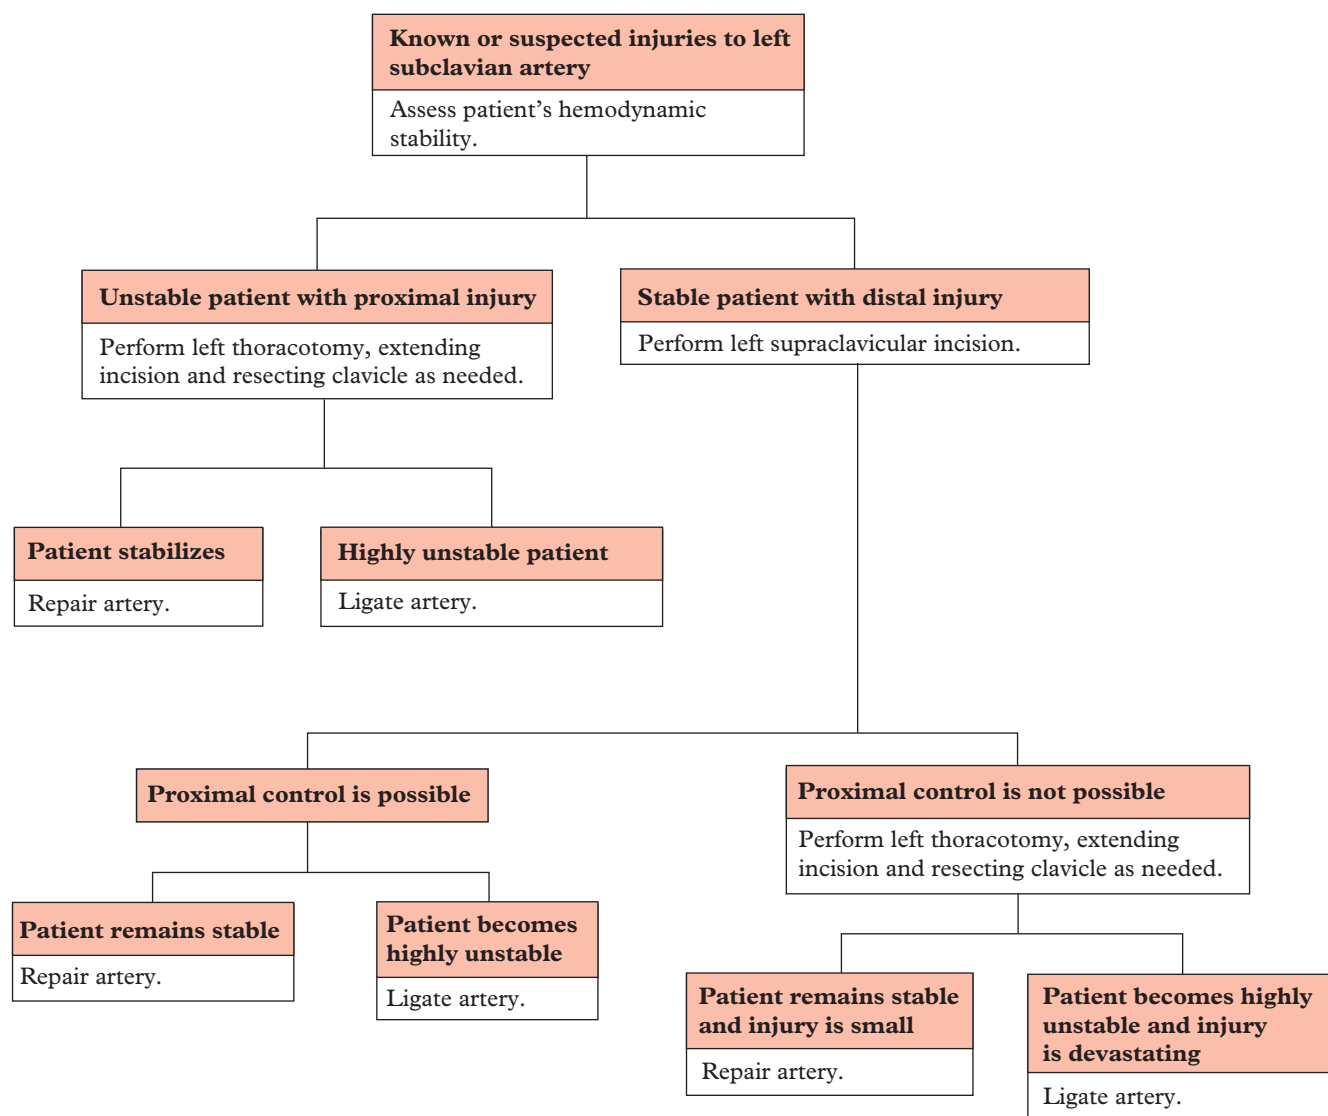

Figure 6 Algorithm outlining management of known injuries to the vertebral artery, which are most often discovered by angiography.

prevertebral muscles is encountered. The ganglia of the cervical sympathetic chain are located here and should be protected, although this is not always possible in emergency circumstances. The anterior longitudinal ligament, located deep in the medial aspect of the wound, is incised longitudinally. The ligament, the underlying periosteum, and the overlying longus colli and longissimus capitis are mobilized anterolaterally with a periosteal elevator [see Figure 7]. The elevation is carried laterally along the lateral margin of the bodies of the cervical vertebrae and along the anterior aspect of the transverse processes of the cervical vertebrae. To avoid injury to the laterally and posteriorly placed cervical nerve roots, the dissection should not be extended laterally beyond the tips of the transverse processes.

After the anterior aspects of the transverse processes of the cervical vertebrae have been exposed, they can be removed with a small rongeur. This should be done distal to the area of injury only; proximal ligation of the vertebral artery can be done in its more easily exposed proximal portion. Although the vertebral artery is also accessible in the spaces between the transverse

processes, there are a number of venous branches in these regions, and it is therefore safer to approach the artery within the confines of the bony foramina.

The third and most distal portion of the vertebral artery is most easily approached between the atlas and the axis. The segment of the artery between the transverse processes of these two vertebrae is longer and more exposed than the segments between the other cervical vertebrae and is therefore, in theory, somewhat easier to expose.

Exposure of the proximal vertebral artery at the base of the neck can also be achieved via an incision along the anterior border of the sternocleidomastoid muscle. Initial exposure is identical to that used for exposure of the carotid arteries. At the level of the carotid sheath, however, dissection is carried lateral to the internal jugular vein, which is retracted medially to expose the supraclavicular fat pad. The proximal vertebral artery can then be controlled after dissection deep to the fat pad, as described for the supraclavicular approach to isolated proximal vertebral artery injuries [see Figure 8].

Figure 7 Throughout most of their course, the vertebral artery and the vertebral veins are surrounded by the transverse processes of the cervical vertebrae. Exposure of this portion of the vertebral artery is best done with anterior and lateral mobilization of the longus colli and the longissimus capitis.

As opposed to injuries of the carotid arteries, in which either repair or ligation is an option, injuries to the vertebral arteries should always be treated with interruption of flow by surgical or other means. Proximal ligation should usually be done at the

Figure 8 Exposure of the distal vertebral artery is done via an incision along the anterior border of the sternocleidomastoid muscle. The sternocleidomastoid muscle is then divided near its origin at the mastoid process. The spinal accessory nerve is mobilized anteriorly. The vertebral artery is accessible after division of the levator scapulae and the splenius cervicis.

origin of the vertebral artery because the approach to the artery at this point is easier than the approaches to the more distal segments. The artery should be suture-ligated as close to its origin as possible so as not to create a thrombogenic blind pouch off the subclavian artery. Distal ligation can be accomplished by first exposing the artery and then ligating with ligatures, suture ligatures, or surgical clips. The use of clips minimizes dissection around the artery, which, in turn, decreases the likelihood of further injury to surrounding veins.

In emergency circumstances, a useful technique is to approach the proximal artery surgically at the base of the neck and pass a thrombectomy catheter distally to the site of injury [see Figure 9]. First, the proximal vertebral artery is exposed and ligated at its origin. Next, the thrombectomy catheter is passed distally via an arteriotomy. The catheter balloon is then inflated, and the wound is checked to determine whether bleeding has been controlled. If bleeding has been controlled, the distal end of the catheter is left in place, and the proximal end is brought out through the wound. The catheter is left in situ for approximately 48 hours, at which time the balloon is deflated and the wound is again checked for bleeding. If there is no bleeding for 4 to 6 hours, the catheter can be withdrawn. Use of a thrombectomy catheter can also serve as a bridge to angiographic embolization. If the thrombectomy catheter technique is unsuccessful, a direct surgical approach to the second or third portion of the artery is necessary. A potential disadvantage of a surgical approach, however, is that proximal ligation of the vertebral artery precludes angiographic embolization except via the contralateral vertebral

Figure 9 Bleeding from vertebral artery injuries located within the transverse process of the cervical vertebrae can sometimes be controlled by exposing the proximal vertebral artery at the base of the neck, passing a thrombectomy catheter distally, and inflating the balloon at the site of injury.

artery. Embolization via the contralateral vertebral artery is difficult and may result in ischemia or uncontrolled embolization.

If the injury is shown by preoperative angiography to be confined to the first portion of the vertebral artery, both proximal and distal ligation may be possible via a supraclavicular incision [see Figure 10]. The patient is positioned with the head turned away from the side of the injury, and the chest and ipsilateral neck are prepared and draped. Preparation and draping include the chest so that a left thoracotomy can be done later if necessary for proximal control of the left subclavian artery. In such cases, it is helpful to bump the patient up on the left so that an anterolateral thoracotomy incision can be carried further posteriorly.

A supraclavicular incision is made approximately one fingerbreadth superior to the clavicle and is extended medially to the midpoint of the sternocleidomastoid insertion and laterally to the juncture of the middle and lateral thirds of the clavicle. The skin, the subcutaneous tissue, and the platysma are incised. The external jugular vein, if in the operating field, is suture-ligated. The clavicular head of the sternocleidomastoid muscle is encountered next, and its lateral aspect is divided with the electrocautery at its insertion on the clavicle. The muscle is then retracted superiorly and medially. In the plane deep to the

sternocleidomastoid muscle, the omohyoid muscle is divided in its middle tendinous portion with the electrocautery.

At a level just deep to the sternocleidomastoid and omohyoid muscles, the carotid sheath is encountered in the medial aspect of the wound. The lateral border of the internal jugular vein is dissected free of adjacent tissue and retracted medially. If the operation is on the left, the thoracic duct may be found in the medial portion of the wound. The thoracic duct is easily injured with retraction and should be divided and ligated if it is obviously in the way.

Just lateral to the internal jugular vein at the same depth is the supraclavicular fat pad, which is dissected from the supraclavicular fossa in which it lies. Exposure is further enhanced by dissection and division of the anterior scalene muscle. The phrenic nerve, which is closely applied to the anterior surface of the anterior scalene muscle, is dissected free of the underlying muscle and retracted out of the field with a vessel loop. The anterior scalene muscle is then divided with the electrocautery. During dissection of the supraclavicular fat pad, it may be necessary to divide branches of the thyrocervical and costocervical trunks. The most prominent of these branches is the inferior thyroid artery, which stems from the thyrocervical trunk and courses medially toward the thyroid.

Figure 10 The proximal vertebral artery can be approached via a supraclavicular incision. Dissection of the supraclavicular fat pad reveals the underlying vertebral artery, where it diverges from the subclavian artery. During dissection, care should be taken to avoid injuring the phrenic nerve.

After the supraclavicular fat pad has been dissected, the proximal portion of the vertebral artery is reached. The vertebral vein, which usually lies slightly superficial and medial to the vertebral artery, is divided and suture-ligated to provide better exposure. Care should be taken not to retract the vertebral vein too vigorously before suture ligation so that this vessel is not avulsed from the subclavian vein. At the depth of the vertebral artery, the white, cordlike elements of the brachial plexus are often visible in the superolateral aspect of the wound. If possible, traction should not be placed on the brachial plexus, and use of the electrocautery around the plexus should be minimized. After exposure, the proximal vertebral artery is ligated both proximal and distal to the site of injury. No attempts at repairing the injury should be made.

Endovascular Repair

Endovascular repair of penetrating carotid artery injuries is still controversial. Advocates have identified it to be beneficial in hemodynamically stable patients with injuries in either the proximal common carotid or the distal internal carotid arteries. Operative exposure of these vessels can be difficult, and instead, a stent graft is used to exclude the injured portion of the artery. Validation of this technique is difficult because of the small number of studies in trauma patients coupled with the challenge of applying the vascular surgery literature to the trauma patient population. Little is known about the long-term effects of carotid stents in relatively young patient populations. Recently, a study has looked at long-term follow-up in a small number of trauma patients.¹⁷ The 30-day stroke rates and mortality were similar to the authors' previously reported open rates. Further study is needed for this technique to gain more widespread acceptance for carotid artery injury.

The use of endovascular embolization in the treatment of distal vertebral artery injuries is more widely accepted than endovascular treatment of carotid artery injuries. Like any endovascular technique, its success depends on the availability of equipment for and expertise with the procedure. Stable patients who have angiographically documented injuries to the distal vertebral artery should be treated if possible with embolization.¹⁸ If angiographic expertise is not available and the patient is stable enough for transfer, it is preferable to send the patient to a center with angiographic embolization capability. In urgent circumstances, an angiographic approach is not practical, and a direct surgical approach is necessary. In practice, rapid exposure of the vertebral artery is very difficult, particularly in an actively bleeding patient.

In cases where angiographic embolization of the vertebral artery has been employed, a postprocedure angiogram should be done several days to weeks after the procedure to ensure that the artery remains occluded and that an arteriovenous fistula has developed between the injured vertebral artery and the surrounding venous plexus. Duplex scanning has also been used to a limited extent for follow-up screening. It can serve as an alternative to angiography, but its sensitivity relative to that of angiography remains to be established.

Jugular Vein Injuries

Any of the veins in the neck can be ligated when necessary. An exception to this rule is the rare instance when both internal jugular veins have been injured, in which case an attempt should be made to repair one of the veins, if possible. Even

in such cases, however, bilateral internal jugular ligation, if necessary, is usually tolerated. It is particularly important to use suture ligatures rather than simple ligatures on the cut ends of the internal jugular vein.

If the injury to the internal jugular is simple, the vein should be repaired. Large jugular vein injuries should be repaired only if the patient's general condition and associated injuries allow; if the patient is hemodynamically unstable or has severe associated injuries, large jugular vein injuries should be treated with ligation.

It is not always necessary to encircle the jugular vein completely both proximal and distal to the site of injury; pressure with a finger or a sponge stick sometimes suffices to control bleeding while simple lateral venorrhaphy is done. In the case of more elaborate repairs, it is better either to encircle and occlude the proximal and distal vein or to place a side-biting vascular clamp for control during repair. Nonabsorbable 4-0 or 5-0 sutures should be used.

Pharynx and Esophagus

The oropharynx, hypopharynx, and cervical esophagus are exposed via the same anterior sternocleidomastoid incision used for arterial and venous injuries. If the patient has a known right-sided injury, the incision should be made in the right neck. If the injury is on the patient's left side or if the exact site of injury is unknown, the exposure should be made from the left because the cervical esophagus is located slightly to the left of the midline. After the initial incision, the contents of the carotid sheath are retracted laterally to expose the lateral aspects of the pharynx and the esophagus. This maneuver is made easier if the anesthesiologist places a large colored esophageal dilator through the mouth. The dilator makes identification of the otherwise flat esophagus easier, and the colored tubing of the dilator can sometimes be seen through defects in the esophageal wall.

Sometimes, a pharyngoesophageal injury is suspected but cannot be confirmed preoperatively. In such cases—especially when the injury is more than 1 or 2 hours old—salivary amylase may be present in the wound, giving the surgeon's gloves a greasy feel. The presence of salivary amylase can be a valuable clue to the existence of an otherwise unknown occult injury.

Injuries to the pharynx and the esophagus may be repaired in either one or two layers with either 3-0 or 4-0 absorbable sutures. Attempts should be made to repair nearly all injuries, even when they are severe or their discovery is delayed. In extreme cases of very large injuries or very delayed operative intervention, it may be necessary simply to drain the neck widely and turn the injury into a cervical esophagostomy. Esophageal diversion with distal esophageal ligation is rarely necessary in patients with isolated cervical esophageal injuries, except when the injury is very low in the neck or in the thoracic esophagus.

Pharyngoesophageal injuries should be drained; either closed or Penrose drainage can be used. The drains should be left in place for approximately 1 week, at which time a radiographic contrast study should be obtained to determine whether the repair is competent. If the contrast study is negative for extravasation and the patient's general status permits, feeding can begin. If the feedings are well tolerated, the drains can be removed.

Patients with pharyngoesophageal injuries should receive several postoperative doses of antibiotics appropriate for oral

flora. If the repair is inadequate or breaks down, the resultant fistula often heals with nonoperative management, provided that drainage is adequate. A high index of suspicion for mediastinitis should be maintained¹⁹; the prevertebral space provides a ready route of access from the pharynx and the cervical esophagus into the mediastinum. Missed or inadequately drained injuries may result in profound infection and a septic response.

Larynx and Trachea

The presence of an isolated laryngotracheal injury is commonly not recognized preoperatively. On occasion, however, isolated injuries to the larynx and trachea are recognized preoperatively on the basis of a suspicious history and the results of diagnostic studies, such as laryngoscopy and bronchoscopy.

Injuries to the larynx that result in airway compromise should be treated initially with a collar incision for the creation of a surgical airway; however, definitive treatment should be deferred. Minimal débridement of laryngeal structures should be carried out during the initial operative procedure. Injuries to the larynx should be handled on a semielective basis by otolaryngologists with expertise in laryngeal repair and reconstruction. Further investigation of the larynx, including laryngeal x-rays, laryngoscopy, and CT, may be necessary. On rare occasions, the injury is in the distal cervical or proximal intrathoracic trachea. In such circumstances, access to the trachea may not be possible through a cervical incision alone. Median sternotomy and lateral retraction of the innominate artery and the left internal carotid artery allow exposure of the anterior surface of the trachea at the thoracic inlet. Right thoracotomy provides access to the more distal intrathoracic trachea.

Small injuries of the trachea should be repaired primarily and may be treated without tracheotomy. These injuries, if not repaired, may lead to drainage of secretions into the mediastinum and result in mediastinitis. Absorbable 3-0 or 4-0 sutures should be placed transversely, if possible, and should include tracheal rings above and below the site of injury. Large anterior defects should be converted to a tracheotomy, whereas defects to the lateral or posterior aspects of the trachea should be closed primarily and protected with a tracheotomy. Tension can be relieved from a repair by mobilizing the trachea proximally and distally. During this mobilization, the recurrent laryngeal nerves are subject to injury if the dissection is carried into the tracheoesophageal groove. Laryngotracheal injuries do not require routine drainage unless there is an associated injury to the pharynx or esophagus.

If a large segment of trachea has been destroyed, primary anastomosis can be accomplished for defects up to five or six tracheal rings in length. A tension-free anastomosis is created by mobilizing the intrathoracic trachea inferiorly and laryngeal complex superiorly.

Patients with laryngeal injuries should be watched carefully in the postoperative period for signs of mediastinitis, which may result from persistent airway leak or a missed pharyngo-esophageal injury. The chest x-ray should also be checked for pneumomediastinum as a sign of continued airway leakage,

particularly in patients who remain on positive pressure ventilation.

Blunt Trauma

Blunt trauma to the neck may not be as dramatic as penetrating trauma, especially with respect to vascular injuries, but may carry just as high morbidity. The basic principles of initial management apply, in accordance with ATLS guidelines: airway, breathing, circulation.⁷ The blunt trauma patient who is unstable with either airway compromise or hard signs of vascular injury needs immediate operative intervention. But, for the majority of patients, a systematic diagnostic workup is required. Patients at highest risk for neck injuries in blunt trauma are those with a direct blow to the neck, signs and symptoms of airway compromise, neurologic deficits, and facial trauma. The approach is similar for penetrating trauma and focuses on the aerodigestive tract, vascular injuries, and the cervical spine.

AERODIGESTIVE TRACT

Blunt injuries to the aerodigestive tract are suspected if there is any subcutaneous air in the neck or mediastinum on the chest radiograph or if any air is seen on CT scan. Once an injury is suspected, endoscopic evaluation similar to that done for penetrating injuries is performed. In contrast to penetrating trauma, injuries to the esophagus after blunt trauma tend to be blowout injuries with larger holes. Contrast esophagrams can detect these injuries easily. Pharyngoscopy and flexible endoscopy can be used to evaluate the oropharynx and airway.

When injuries are discovered with panendoscopy or contrast esophagoscopy, repair is done in a fashion similar to that described in the penetrating trauma section. The basics include débridement of devitalized tissue, repair, and drainage. There is a risk of abscess and mediastinitis if aerodigestive injuries go unrecognized or are not treated. The exceptions are small oropharyngeal injuries.

Small oropharyngeal injuries, if they are detected, can be treated with antibiotics and observation for developing infection. These injuries can be difficult to approach operatively and usually heal on their own. If the wounds are large or there is an associated cervical spine injury that requires open reduction and internal fixation, operative repair should be undertaken.

CEREBROVASCULAR INJURIES

Blunt injuries to cervical arteries, although relatively rare, can be difficult to diagnose and can lead to devastating complications (e.g., stroke and bleeding). Most such injuries result from stretching of the vessels as a consequence of hyperextension of the neck.²⁰ Motor vehicle collision is a common cause of this sort of stretch injury. Injury may also be caused by direct trauma to the artery, such as with a seat belt or by fracture fragments, particularly cervical transverse foramen or basilar skull fractures.²⁰ Arterial stretching leads to endothelial tearing, with subsequent intimal flaps, dissections, or emboli.

The true incidence of blunt cervical vascular injury is unknown. Recently, aggressive screening has put the incidence at 1 to 2% of all blunt trauma patients, with higher rates in specific patient populations.²¹ Patient populations at

highest risk for blunt cervical artery injury are those with signs and/or symptoms of injury (i.e., seat-belt mark, expanding hematoma,²² neurologic deficit²²), with certain mechanisms of injury (i.e., near-hanging), or with other specific head or neck injuries (basilar skull fracture).²³ When aggressive screening is employed, approximately 3 to 5% of blunt trauma patients undergo workup and approximately 30% of the workups reveal an injury.²⁴

Four-vessel angiography has historically been the gold standard for imaging the cervical vasculature but is invasive and expensive and has largely been replaced as a screening modality by CT angiography.²⁵ CT angiography is noninvasive can be performed relatively rapidly and can be done in the course of CT scanning of the head and other parts of the body. Improvements in CT technology, particularly the use of multidetector CT scanners, have resulted in sensitivity and specificity rates similar to those of formal angiography.^{26,27}

Biffi and colleagues developed a grading scale for blunt cervical arterial injury based on the angiographic appearance of the lesion.²⁸ On this scale, grade I and II lesions show less than 25% and greater than 25% luminal narrowing, respectively; grade III lesions are pseudoaneurysms; grade IV lesions demonstrate thrombosis; and grade V lesions are transections with extravasation. Grade I to III lesions may progress to a higher grade over time.²⁰

Treatment of blunt cervical arterial injury reduces morbidity and mortality. Groups in Denver and Memphis have shown a dramatic decrease in stroke rates (54% to 2.6% and 64% to 6.8%, respectively) for carotid artery injuries in treated versus untreated patients.²⁹ Although treatment of some sort seems to be beneficial, the exact means of treatment is debated. The primary goal of treatment is to decrease embolic events, and the most common treatment is some means of interfering with clotting, which can be challenging in trauma patients with contraindications to anticoagulation, such as intracranial hemorrhage, solid organ, or pelvic injuries. The risks and benefits of anticoagulation versus simple observation and expectant management need to be weighed.

Asymptomatic patients with small intimal flaps or minimal dissection who have no contraindication to antiplatelet agents should be given aspirin. If a contraindication to aspirin exists, the patient should be treated expectantly. More than half of low-grade injuries heal within 2 weeks, and anticoagulation can be stopped after 14 days. If the patient is asymptomatic but has an acute dissection with no contraindications to anticoagulation, then either heparin or antiplatelet agents should be given. Patients with neurologic symptoms need to be anticoagulated. If there is an enlarging pseudoaneurysm or

a contraindication to anticoagulation, operative or endovascular intervention should be performed.²⁰

Endovascular techniques have been used increasingly for the treatment of blunt carotid injuries, most commonly for pseudoaneurysms, especially in the distal portions of the internal carotid, where open repairs are made difficult by the skull base. DuBose and colleagues reported 76% success rates in the placement of endovascular stents in the carotid artery, with close to 80% patency rates at follow-up.³⁰ They reported a stroke rate of 3.5%, which is similar to that seen after open procedures.

Follow-up for blunt carotid injuries is based on grade and treatment modality. Grade 1 and 2 injuries can be reevaluated at discharge, if at all, because the majority heal. Grade 3 injuries require anticoagulation or antiplatelet treatment for up to 8 weeks and then should be reimaged. Approximately a third of all grade 3 injuries progress and may require delayed endovascular or operative intervention.²⁰ Grade 4 and 5 injuries, because of their devastating nature, are typically treated at presentation and should have routine and regular follow-up of the repair.

VERTEBRAL ARTERY

Blunt vertebral artery injuries are often associated with cervical spine fractures.³¹ Most patients with blunt vertebral artery injuries are stable, experience no external bleeding, and have their injuries discovered by angiography or CT angiography. A number of such lesions have been successfully treated with angiographic embolization. Given the difficulties of surgical exposure, lesions of the distal vertebral artery, if characterized by active extravasation, pseudoaneurysm, or arteriovenous fistula, should be treated angiographically when the patient's general condition permits and when the necessary expertise is available. If the patient is bleeding profusely, such an approach is not possible and a rapid surgical approach is indicated, with ligation of the proximal vertebral artery and an attempt at thrombectomy catheter control or packing of the wound until an angiographic approach is attempted. If this is unsuccessful, the lesion should be approached directly. If a patient with a distal vertebral artery lesion is stable—particularly when the lesion is otherwise silent and has been detected angiographically—an attempt should be made at angiographic embolization if the necessary expertise is available. If the patient is stable, transfer to the nearest center with cerebral angiographic embolization capability is appropriate. Embolization is done via the ipsilateral proximal vertebral artery. Detachable balloons or coils can be used.

5 INJURIES TO THE CHEST

J. Jason Hoth, MD, FACS, Edward H. Kincaid, MD, FACS, and J. Wayne Meredith, MD, FACS

Chest trauma as a result of blunt or penetrating mechanisms is highly prevalent and associated with significant morbidity and mortality. Thoracic injuries are a primary or contributing cause of death in up to 75% of all trauma-related deaths.^{1,2} Fortunately, the majority of thoracic injuries can be treated effectively, and often definitively, by relatively simple maneuvers that can be learned and performed by most physicians involved in early trauma care. However, approximately one in six patients has severe, life-threatening injuries that necessitate urgent operative repair. These extremes in injury severity are unique to the chest and require a correspondingly broad range of knowledge and skills on the part of the treating surgeon.

Initial Evaluation and Management

PRIMARY SURVEY

Initial evaluation and treatment of patients with thoracic injuries are guided by the same principles and priorities as initial evaluation and treatment of patients with other injuries. Evaluation begins with an organized and rapid primary survey aimed at recognizing and treating immediately life-threatening problems.

The first priority is to ensure an adequate airway. An airway often can be established by clearing any blood or debris from the oropharynx and pulling the mandible or the tongue forward. Severely injured patients commonly require nasotracheal or orotracheal intubation, and some, especially those with severe maxillofacial trauma, may require cricothyroidotomy or tracheostomy. The second priority is to ensure adequate ventilation. If the patient is not breathing, he or she must be intubated promptly. If ventilation is inadequate because of open or tension pneumothorax, these problems should be addressed at this stage of care.

The next priority is control of external hemorrhage and restoration of circulation. External hemorrhage is best controlled by direct pressure. Inadequate perfusion generally results from either hypovolemia or pump (i.e., cardiac) problems. Hypovolemia from hemorrhage, by far the most common cause of inadequate perfusion in the traumatic setting, often must be treated operatively as part of the resuscitative effort. Pump problems are signaled by distended neck veins and are caused by one of four conditions: (1) tension pneumothorax, (2) pericardial tamponade, (3) coronary air embolism, or (4) cardiac contusion or myocardial infarction (MI). These conditions are discussed in detail elsewhere (see below). At this early stage of treatment, they should be addressed sufficiently to ensure adequate perfusion.

In most blunt trauma patients, urgent treatment of thoracic injury is accomplished during the primary survey because the most common blunt chest injuries can be controlled with

endotracheal intubation or tube thoracostomy. In this setting, thoracotomy is indicated for cardiac tamponade, a massive hemothorax, or uncontrolled massive air leaks. Neither pulmonary nor cardiac contusions should delay diagnosis or definitive treatment of extrathoracic injuries resulting from blunt trauma.

TUBE THORACOSTOMY: INDICATIONS AND TECHNIQUE

During initial resuscitation, chest tube placement can be both therapeutic and diagnostic. The two most common indications for tube placement in this setting are pneumothorax and hemothorax; however, signs and symptoms of these conditions may not be readily apparent during the initial evaluation of the patient. In addition, when the patient is in shock, the surgeon often cannot afford to take the time to differentiate between various possible causative conditions. Because tube thoracostomy is quick, relatively safe, and simple, it should be liberally used for patients in extremis or with pulseless electrical activity.

Tension pneumothorax, the most common and easily treated immediately life-threatening thoracic injury, results when blunt or penetrating trauma disrupts the respiratory system and allows air to escape from the lung parenchyma or the tracheobronchial tree into the pleural space, thereby increasing intrathoracic pressure. This increased pressure is transmitted to all the cardiac chambers and retards venous return to the heart, resulting in hypotension. The classic signs of tension pneumothorax—decreased breath sounds, tympany on the ipsilateral side, tracheal shift, and distended neck veins—are commonly absent or are incompletely manifested in a busy emergency department (ED). The diagnosis is often suggested by the presence of shock accompanied by evidence of inadequate venous filling on physical examination and recognition of diminished breath sounds and asymmetrical motion of the two sides of the chest. Treatment of a suspected tension pneumothorax should not be delayed in patients with hemodynamic compromise.

Chest tube placement in the trauma setting requires the chest to be prepared and draped in a sterile fashion. A local anesthetic (e.g., 1% lidocaine) is not required in unconscious patients but should be used in alert patients. On the midaxillary line in approximately the fifth interspace, a scalpel is used to make a 2 to 3 cm incision, oriented in the direction of the interspace, through all layers of the skin and subcutaneous tissue. A finger or a blunt clamp is inserted to penetrate the intercostal muscles and the parietal pleura. The wound is explored with the index finger (in adults) or the fifth finger (in children) to ensure that the pleural space has been entered. In adults, a 36 French chest tube is then inserted and advanced posteriorly, toward the apex of the thoracic cavity, for optimally effective drainage of air and blood. The desired tube position is best achieved through appropriate

orientation of the skin incision relative to the entrance into the chest cavity: the straight line between these two points defines the direction of the tube once it is in the chest. The tube is then attached to 20 cm of suction with a water seal and a collection chamber. Visual inspection of air passing through the water seal yields an estimate of the size of the air leak, an important consideration with suspected airway injuries.

Collection chambers for hemothoraces should be of the same design. Those associated with autotransfusion devices (e.g., cell savers) have immense theoretical potential for rapid retrieval and processing of shed blood. However, their utility is limited. For example, with a small to moderate-size hemothorax (< 1,000 mL), the red cell yield of an autotransfusion device would be small and not worth the associated time and expense. With a large hemothorax, the most important goal of therapy is control of bleeding, and arranging for autotransfusion could delay or hinder the achievement of this goal. In addition, the collection system uses heparin, and delivery of the products is limited by the pore size of the filtration device (40 to 100 μ m), making rapid delivery difficult. Furthermore, products of autotransfusion may contain harmful cytokines, damaged cells, and debris, while lacking platelets and other important proteins and coagulation factors. Given these factors, in our practice, autotransfusion is rarely used in the acute setting.³ Antibiotic prophylaxis after tube thoracostomy is controversial.⁴ Practice guidelines from the Eastern Association for the Surgery of Trauma currently recommend use of a first-generation cephalosporin for no more than 24 hours, ideally starting before the initial tube placement in cases of isolated chest trauma.

After the primary survey, less dramatic pneumothoraces may be recognized on diagnostic images, along with hemothoraces on various imaging studies. Treatment of occult pneumothoraces (i.e., those seen only on computed tomography [CT]) deserves special mention. In general, patients with occult pneumothoraces who require positive pressure ventilation, those who are hypotensive or have respiratory distress of any etiology, and those who have associated complex injuries or hemothorax should be treated with tube thoracostomy. One group, however, has questioned the need for tube thoracostomy in patients requiring positive pressure ventilation on the basis of findings from a small number of patients.⁵ Patients with occult pneumothoraces who are treated without tube thoracostomy should be observed for at least 24 hours with repeat chest radiography to ensure that the pneumothorax has not enlarged.

Retained Hemothorax and Empyema

 In treating a hemothorax with tube thoracostomy, the goal is complete evacuation of blood from the pleural space and complete expansion of the lung. Complications such as atelectasis and empyema after chest trauma are clearly related to the presence of residual blood, fluid, and air, as can occur secondary to improper positioning (i.e., within a fissure) or obstruction of the tube. A retained hemothorax is suggested by the presence of a persistent opacification in the pleural space in a patient with a known previous hemothorax. However, plain chest radiography can be misleading, often underestimating the amount of fluid in the chest, and the radiodensity seen can be confused with adjacent pulmonary

contusion or atelectasis. Chest CT confirms the diagnosis, providing information about the size and location of the hemothorax that can be used intraoperatively to make the appropriate incision. Because retained blood serves as a nidus for infection and empyema,⁶ aggressive attempts at removal are justified. Particularly after penetrating trauma, placement of additional chest tubes is rarely effective in removing clotted blood from the pleural space and may increase the risk of infection.⁷ Thus, an operative approach is needed. When used early (less than 5 days after injury), video-assisted thoracic surgery (VATS) is a cost-effective method for managing clotted hemothoraces and free-flowing blood in patients who ideally can tolerate single-lung ventilation.^{8–10} However, VATS may limit the surgeon's ability to control bleeding and perform definitive repair of injuries; thus, in patients who have ongoing bleeding, posterolateral thoracotomy is required. It is our practice to routinely obtain chest CT within 48 hours of injury when patients have persistent pleural effusion on chest radiography within 48 hours of injury. In patients confirmed to have a persistent pleural effusion limiting lung expansion, we proceed directly to VATS. It is well documented that delaying the operation increases the technical difficulty of the procedure and rate of conversion to thoracotomy.¹¹

Empyema thoracis is a relatively common complication after chest trauma, occurring in 5 to 10% of patients.^{12,13} Possible causes include retained hemothorax, pneumonia with parapneumonic effusion, persistent foreign body, ruptured pulmonary abscess, bronchopleural fistula, esophageal leakage, and tracking through the intact or injured diaphragm from an abdominal source. Empyema may be difficult to diagnose in the posttraumatic setting and must be differentiated from pleural thickening, pulmonary contusion, and an uninfected effusion. Chest CT with intravenous (IV) contrast usually demonstrates a fluid collection with loculations or an enhancing rim. Such findings, coupled with a clinical scenario of low-grade sepsis, worsening respiratory function, or failure to thrive, are diagnostic. Analysis and culture of fluid obtained at thoracentesis or chest tube placement typically confirm the diagnosis, but the fluid may be sterile if the patient is already receiving antibiotics.

Antibiotic therapy, either broad spectrum or specifically directed against cultured organisms (usually gram-positive pathogens), is certainly an important component of therapy for empyema thoracis, but the primary goal is removal of the infection while the fluid is still thin. When this goal is met, a more modest therapeutic procedure can be performed, there is less risk that a restrictive pulmonary peel will develop, and the injured patient recovers faster overall. Rarely, in the early stages, tube thoracostomy may suffice for treatment; however, more commonly, the infected pleural process cannot be completely evacuated via chest tube because of thicker fluid, loculations, or pleural adhesions. In these cases, VATS or a formal thoracotomy with decortication is generally required.

Decortication is the cornerstone of effective therapy for posttraumatic empyema. Emphasis should be placed on completely removing the visceral pleural peel to allow complete lung expansion postoperatively. Decortication should not be undertaken in the face of severe sepsis. Instead, antibiotics and drainage (via tube thoracostomy, CT-directed catheter

placement, or open rib resection) should be employed until sepsis is controlled. Once the patient's condition has stabilized, decortication may be performed. In cases of early empyema, VATS has been successfully used for lysis of adhesions and removal of fluid.^{14,15} Because of the limited capacity for performing pleurectomy with this procedure, VATS should not be used when thick peel or a trapped lung is present. In adult patients with posttraumatic empyema, there is no proven role for intrapleural fibrinolytic therapy.

EMERGENCY DEPARTMENT RESUSCITATIVE THORACOTOMY

Emergency department resuscitative thoracotomy (EDRT) is a drastic step in the treatment of the injured patient. If possible, the patient should be stabilized and transported to the operating room (OR), where better facilities are available for definitive care. EDRT is best reserved for patients who arrive at the ED and deteriorate rapidly and those who have undergone cardiac arrest just before arrival. EDRT is futile care when performed in the face of prehospital cardiopulmonary resuscitation of greater than 10 minutes in the setting of blunt trauma and 15 minutes after penetrating trauma or when the presenting rhythm is asystole. Overall, the survival rate for patients undergoing EDRT for blunt trauma is approximately 1%.¹⁶ Survival rates are better for patients undergoing EDRT after penetrating trauma, with reported rates from 16 to 57%, and those for patients with cardiac wounds range from 57 to 72%.^{17–19} Better outcomes are seen when performed for stab wounds rather than gunshot wounds.

The technique of EDRT ideally requires that an antiseptic solution be splashed on the chest, but skin preparation is not required. A left anterolateral thoracotomy incision is made from the sternal border to the midaxillary line in the fourth intercostal space. A chest retractor is inserted and opened widely. The costochondral junctions of the fifth, the fourth, and sometimes the third rib are divided quickly with the scalpel to provide exposure. The six main therapeutic goals are (1) confirming endotracheal intubation; (2) control of hemorrhage; (3) relief of cardiac tamponade if present; (4) effective cardiac compression; (5) cross-clamping the pulmonary hilum in the case of major lung hemorrhage, air embolism, or massive bronchopleural fistula; and (6) cross-clamping of the descending aorta for lower torso hemorrhage control. Attention is directed first to the injury. If there is exsanguination from a great vessel, the hemorrhage is controlled with pressure. If air embolism is the cause of the arrest, the hilum is clamped and air is evacuated from the aorta. Otherwise, the pericardium is opened anterior and parallel to the phrenic nerve. The hemopericardium is evacuated, the cardiac injury is controlled with digital pressure, and a temporary repair is performed. After the cause of the arrest has been addressed, the descending thoracic aorta is occluded with a vascular clamp or digital pressure and intrathoracic cardiac compression is initiated. The patient's intravascular volume is restored, and electrolyte imbalances are corrected. If the patient can be saved, he or she is transported to the OR for definitive repair and closure.

SECONDARY SURVEY AND DEFINITIVE DIAGNOSIS

The secondary survey should focus on more subtle evidence of injury that may be detected on physical examination

and chest x-ray. Simple rib fractures are clinically relevant when associated with pain and are better diagnosed by palpation than by most imaging studies. Pneumothorax and hemothorax often go undetected during the primary survey but are common findings later in the workup.

Echocardiography can be an important adjunct for assessing proximity wounds to the heart or evaluating a new murmur. Because of continuing improvements in CT technology, this modality is increasingly being used in the evaluation of thoracic trauma in stable patients.²⁰ Indeed, CT angiography is now routinely employed for definitive diagnosis of aortic and great vessel injuries, rendering standard angiography unnecessary in most cases.²¹ Additionally, CT is also useful in the diagnosis of tracheobronchial and esophageal injuries.^{22,23}

Operative Considerations

INDICATIONS FOR OPERATIVE MANAGEMENT

Indications for operative treatment of thoracic injuries fall into five broad categories: (1) hemorrhage, (2) major airway disruption, (3) cardiac and vascular injuries, (4) esophageal disruption, and (5) diaphragmatic disruption. **The extent and location of hemorrhage can sometimes be determined from open wounds but are more often established after chest tube insertion. If 1,500 mL of blood or more is obtained initially or ongoing bleeding at a rate of 300 mL/hr or higher for 3 hours is noted, thoracotomy is generally indicated.**²⁴ Caveats to the use of chest tube drainage as an indicator for chest explorations are chest trauma with a delayed presentation and the presence of a coagulopathy. Patients presenting with chest trauma in a delayed fashion may have a significant hemothorax that has accumulated in the time it has taken the patient to arrive in the ED. Furthermore, previously placed chest tubes may become clotted, allowing accumulation of a hemothorax prior to arrival. In these situations, placement of a second chest tube and/or evidence of ongoing bleeding rather than an absolute amount may be a more reliable indicator of the need for thoracic operation.²⁴ Additionally, another group of patients in whom caution should be exercised are those who have significant chest wall injury and a coagulopathy attributable to closed head injury or preinjury medication. Thoracotomy in this setting is frequently not therapeutic.

Massive air leakage and the presence of gastric or esophageal contents in the chest tube effluent also necessitate surgical intervention. **The severity of an air leak can be estimated by examining the amount of air traversing the water seal chamber. Intermittent bubbling signifies a small leak, whereas a continuous stream of bubbles signifies a large leak. A continuous leak seen in conjunction with inability to expand the lung completely or with inadequate tidal volumes is considered a massive air leak. In stable patients with no evidence of bleeding, specific diagnostic measures may be performed to evaluate the thoracic viscera. The likelihood of associated intra-abdominal injuries must not be overlooked.**

CHOICE OF INCISION

The choice of thoracic incision obviously depends on many factors, including the indication for operation, the

urgency of the situation, the presence of associated injuries, the mechanism of injury, and the results of preoperative studies. For injuries that are suspected or diagnosed preoperatively, the choice of the appropriate approach to the affected thoracic structure is greatly simplified [see Table 1]. For exploratory surgery, the choice of incision is more complex and should depend on the mechanism, the instrument, the location (of the entire injury, not just the entry site), and the symptoms. Stab wounds generally have a lower potential for deep penetration than missile injuries do.

A median sternotomy is one of the more versatile thoracic incisions. It can be opened and closed more quickly than a thoracotomy, is associated with less postoperative pain, and may be less likely to result in contamination of the dependent hemithorax. In general, a median sternotomy provides the best exposure of the right-side cardiac chambers, the ascending aorta, the aortic arch, and the arch vessels (excluding the left subclavian artery), and it provides adequate exposure of both lungs and both hemidiaphragms. In the setting of exploratory surgery, a median sternotomy is the best incision for mantle stab wounds and some precordial gunshot wounds whose trajectory can be reliably determined. Its main

limitation is that it does not provide exposure of the posterior mediastinal structures.

For exploration of lateral stab or gunshot wounds, a posterolateral thoracotomy on the side of the injury is the incision of choice. Besides being the best incision for exploratory purposes, the fifth interspace thoracotomy is the most versatile approach to ipsilateral pulmonary and mediastinal pathologic states. Exposure can be markedly enhanced by removal of the fifth rib, which yields an incision that is as long as the rib itself and extends as high as the fourth interspace and as low as the sixth interspace. In general, it is unwise to perform an exploratory thoracotomy below the fourth interspace or above the sixth. A transverse anterior thoracotomy (clamshell incision) is occasionally useful for undetermined or transmediastinal injuries in urgent situations. When exposure of both hemithoraces is required in nonurgent situations, both staged bilateral posterolateral thoracotomies and median sternotomy provide better exposure; one or the other is therefore preferred.

The role of VATS in the trauma setting continues to evolve. In acute situations, VATS is useful for ruling out diaphragm injury and may be preferable to laparoscopy insofar as it is

Table 1 Surgical Approaches for Traumatic Injuries to Thoracic Structures

Site of Injury	Incision		
	Sternotomy	Right Thoracotomy	Left Thoracotomy
Right atrium	+++	++	0
Right ventricle	+++	+	+

less likely to cause tension pneumothorax. VATS may also have a role to play in the management of persistent intercostal or internal mammary artery bleeding, but this application demands some degree of experience with thoracoscopic surgery. **Later after injury, VATS can be employed for evacuation of retained hemothorax or for management of the early stages of empyema.**

DAMAGE CONTROL TACTICS

Whereas the concept of damage control is critically important in abdominal trauma, it is less important in thoracic trauma. In most instances, serious bleeding from thoracic structures is unlikely to be controlled with packing; however, severe coagulopathy occasionally prevents definitive repair and necessitates abbreviation of surgery and temporary closure of the chest by suturing or stapling the skin incision only.²⁵ The two most common locations of injury in these scenarios are the lung and the chest wall. Hemorrhage from lung lacerations in patients with metabolic exhaustion generally should not be treated with formal anatomic resection: stapled wedge resection, tractotomy, or simple suture repair is more appropriate. In patients with persistent chest wall bleeding that is not associated with a major vessel, treatment with lung reexpansion for local tamponade and correction of coagulopathy usually suffices. Patients in whom an air embolus occurs, most commonly immediately after intubation, or who have massive bronchopleural fistula will require clamping or “twisting” of the pulmonary hilum on the affected side so that the patient may be stabilized prior to proceeding with definitive operation. In rare circumstances, complex esophageal injuries may be associated with extensive loss of tissue, necessitating rapid exclusion and proximal diversion. In most patients with any chance of survival, however, the surgeon should attempt primary closure of the injury, buttressing the repair with autologous tissue and employing wide drainage. Even with large defects, this approach has a surprisingly high rate of ultimate success.

ANESTHETIC CONCERNS

Air embolism seen in the acute traumatic setting is a left heart embolus rather than the more commonly seen right-side embolus. In the setting of traumatic air embolus, there are no anesthetic concerns that should be addressed in contradistinction to right heart emboli.

Airway management can be extremely complex in patients with thoracic injuries, especially when tracheobronchial injury is involved. Whenever operative management is required for a thoracic trauma patient, operative planning should begin with a discussion with the anesthesiology team about airway issues.

In general, double-lumen and bronchial-blocker endotracheal tubes, which allow better exposure by partially or completely deflating a selected lung, should be strongly considered for any thoracic operation. For any given patient, the improved exposure achievable with such tubes must be weighed against the disadvantages, namely, the additional time needed for placement and the requirement that single-lung ventilation be tolerable from a cardiopulmonary standpoint. Hemodynamic stability, therefore, is usually a prerequisite for the use of these devices. The extent of the advantage gained with lung isolation must also be considered.

For example, surgery on the mediastinum or the hilum is greatly facilitated by lung deflation, whereas surgery on the chest wall is not.

If, at presentation, a patient with an otherwise adequate airway has signs of airway injury (e.g., a massive air leak, subcutaneous air, or hemoptysis), further evaluation with bronchoscopy in the OR is indicated before a decision is made to replace the existing adequate airway. In the absence of massive air leakage, bronchial tearing, or hemorrhage into one mainstem bronchus, a double-lumen tube should be advanced into the left mainstem bronchus. Otherwise, the tube should be placed so as to protect the uninjured side.

When a patient with a double-lumen tube in place requires continued intubation after operation, the tube generally must be replaced with a standard endotracheal tube or a tracheostomy because an adequate pulmonary toilet cannot be performed through a double-lumen tube. In contrast, a bronchial-blocker tube may be left in place after surgery because a suction catheter can be passed down it. A disadvantage of the bronchial-blocker tube, however, is that intraoperative lung isolation may be less complete than that obtained with a double-lumen tube.

When a patient requiring a thoracic operation presents with an inadequate airway, specific airway management depends on the nature of the injuries. Most of these patients can be intubated in the standard fashion. If intubation is unsuccessful, however, cricothyroidotomy should be attempted without delay. In cases of tracheal transection, the distal segment must be controlled quickly through a neck incision and selectively intubated through the wound. In cases of known or suspected thoracic airway injuries, an endotracheal tube should be inserted over a bronchoscope past the injury or into an uninjured mainstem bronchus.

Intraoperative management of the airway in patients with complex tracheobronchial injuries can be challenging and is discussed in detail elsewhere [see Tracheobronchial Injuries, *below*]. Injuries to the thoracic trachea may necessitate placement of temporary tubes within the operative field to provide ventilation [see *Figure 1*]. After repair of a tracheobronchial injury, the patient should be extubated if at all possible to prevent stress on the repair.

The locations of arterial catheters should be considered as well. In general, radial arterial lines should be placed in the extremity opposite the side of the intended thoracotomy and not (obviously) in vessels distal to anticipated cross-clamps. Placement of an epidural catheter for postoperative pain management should also be considered in patients undergoing nonurgent thoracotomy.

Control of body temperature is critical for both operative and nonoperative management. Most thoracic trauma patients are hypothermic and require a warm OR, warm IV fluids, and warming blankets. Occasionally, controlled hypothermia is a useful adjunct to procedures involving the thoracic aorta when spinal cord injury and paraplegia are risks. For patients with severe coagulopathy and a core temperature lower than 33.5°C (92.3°F), extracorporeal warming can be lifesaving. This procedure involves placement of a 21 French femoral venous cannula and a 17 French internal jugular cannula and use of a centrifugal pump and a heat exchanger. Heparin is not necessary.

Figure 1 Intraoperative placement of an endotracheal tube is useful for airway management in patients with tracheobronchial injuries.

Chest Wall Injuries

BLUNT

The greatest significance of certain chest wall injuries is their frequent association with other, more life-threatening injuries. These so called sentinel injuries include first rib fractures, scapular fractures, sternal fractures, bilateral rib fractures, and lower fractures.

Simple Rib Fractures

Rib fractures are the most common chest wall injuries resulting from blunt trauma. The main pathophysiologic consequences of rib fractures are pain, splinting, and prevention of adequate cough. The diagnosis should be suspected if pain or splinting occurs on deep inspiration and is confirmed by careful physical examination, consisting of anterior-posterior and lateral-lateral manual compression. If an alert patient feels no pain when these maneuvers are done, clinically significant rib fractures can be excluded. Although rib fractures are often identified on routine chest radiographs, they are more likely to be undetectable except on rib-detail films, which are rarely indicated. A variant of rib fracture that falls into the same physiologic category is costochondral or costosternal separation. This condition is usually detected during physical examination but is not seen on routine chest radiographs.

Management Pain control for isolated rib fractures can usually be adequately accomplished with oral analgesics, encouraging good pulmonary toilet, and use of thoracic epidural anesthesia (discussed below) in select patients. We mention chest wall strapping, taping, and bracing only to condemn these practices. Binding devices generally restrict tidal volume and thus promote rather than prevent atelectasis and pulmonary complications. Increasingly, reports have demonstrated the feasibility of rib fracture repair using a variety of different methods, including wire sutures, intramedullary wires, staples, and various plating systems.²⁶ Potential indications for operative repair of rib fractures include flail chest (as discussed below), painful moveable rib fractures that are refractory to conventional management, chest wall deformity or defect, rib fracture nonunion, and during thoracotomy for other indications. In isolated reports, clinical outcomes have been excellent when repair is undertaken, and most trauma surgeons feel that there is a role for rib repair; however, there is a need for clinical trials documenting the superiority of rib fracture repair versus conventional management in select patient populations.^{27,28}

Special mention should be made of rib fractures in the elderly. The mortality associated with rib fractures is twice as high in patients older than 65 years as in younger patients, and the relative increase in the incidence of pneumonia in older patients is even higher, even after the increased comorbidity is taken into account.^{29,30}

Sternal Fractures

The vast majority of sternal fractures result from motor vehicle accidents and are associated with the use of three-point restraints. Isolated sternal fractures in this setting are relatively benign, with a low incidence of associated cardiac, great vessel, and pulmonary injuries. Sternal fractures in

unrestrained occupants and victims of crush injuries, however, are commonly associated with underlying visceral injuries, which must be excluded.³¹

The diagnosis of sternal fracture is based on the presence of severe pain, often associated with instability on sternal palpation. In many cases, physical examination can clarify the nature of the fracture. Sternal fractures are almost invariably transverse, with the majority occurring at the sternomanubrial joint or in the midbody of the sternum. They may be characterized as simple (two fragments) or comminuted (multiple fragments), as displaced or aligned, or as stable or unstable. The fragments of an unstable fracture move substantially with activity.

Management Initial management of a sternal fracture is directed toward resuscitation and identification or exclusion of other life-threatening injuries. In patients with isolated sternal fractures, a normal electrocardiogram (ECG) and a normal chest radiograph suggest that associated serious injuries are unlikely. If the pain is controlled with oral analgesics, these fractures can usually be managed on an outpatient basis. Displaced fractures may be reduced by the simple (albeit painful) maneuver of having the patient simultaneously raise his or her head and legs from the bed. Such a position requires contraction of the rectus abdominis, which distracts the caudad segment inferiorly, and the sternocleidomastoid muscles, which retract the cephalad segments superiorly. The physician can then depress the anterior segment and allow the patient to relax. This measure often suffices for alleviation of subsequent pain and sometimes constitutes adequate long-term treatment.

The vast majority of sternal fractures heal with nonoperative management. Those that are unstable or are displaced by more than 1 cm of overlap are more likely to exhibit malunion or nonunion and subsequent chronic pain; they should be treated with open reduction and internal fixation. Occasionally, a patient with a clinically stable, minimally displaced sternal fracture associated with lower extremity injuries who requires crutches for ambulation experiences such disabling sternal pain during ambulation that fracture repair is necessary.

Sternal fractures may be repaired with either of two operative techniques. In both, the sternum is approached via either a vertical midline incision or a sweeping transverse inframammary incision similar to that used for repair of pectus excavatum. The fracture is exposed, and the ends are mobilized and fixed with either reconstruction plates or No. 6 sternal wires. Reconstruction plates provide a more stable and less painful fixation and can be used in the management of comminuted and crush fractures. Wire repair is unsatisfactory in patients with comminuted or crush fractures and in many patients requiring crutches for ambulation. Both wire fixation and plate fixation are well tolerated and, in fact, greatly appreciated by properly selected patients.

Flail Chest

Flail chest is the most serious of the blunt chest wall injuries. It is common after any form of blunt thoracic trauma, and although it may occur as an isolated finding, it is usually associated with other significant injuries.³² Flail chest represents a disruption of the stability and normal respiratory

mechanics of the rib cage. It involves fractures of adjacent ribs, each of which is fractured in two or more places, so that a panel of chest wall moves independently of, and in the opposite direction to, the remainder of the chest. When it occurs in conjunction with separation of the costochondral or costosternal joints, the sternum can also be part of the flail segment, and the condition is termed a sternal flail chest.

The following are the three components of the pathophysiology of flail chest:

1. *Alteration of chest wall mechanics.* The paradoxical motion of a large flail segment occasionally impairs the patient's ability to achieve an adequate tidal volume or an effective cough.
2. *Underlying pulmonary contusion.* In the vast majority of serious flail chest injuries, this is the most significant physiologic aberration. In the contused portion of the lung, there is extravasation and accumulation of blood and fluid in the alveolar air space, which results in sufficient shunting to produce hypoxemia.
3. *Pain.* The extreme pain of multiple rib fractures leads to profound splinting and diminution of tidal volume and prevents adequate coughing and pulmonary toilet in most alert patients. The combination of depressed tidal volume and inadequate coughing leads to hypoventilation, atelectasis, and often pneumonia.

The diagnosis is typically suspected on the basis of the presence of numerous adjacent rib fractures on a chest radiograph [see Figure 2] but can be conclusively confirmed only by

Figure 2 Chest x-ray and three-dimensional reconstruction of a patient with flail chest.

the presence of a paradoxical motion observed in the involved segment in a spontaneously breathing patient. A flail segment may be overlooked in a patient on positive pressure ventilation because there may be no paradoxical motion without inspiratory effort. Therefore, in an intubated patient, the diagnosis must be sought through careful examination and palpation of the rib cage for stability.

Management Proper management of flail chest hinges on the recognition that the injury is not a static condition but, rather, an evolving process. Frequent reevaluation and timely, appropriate intervention are essential. During the initial assessment, the patency of the airway and adequacy of ventilation must be established or confirmed. Immediate intubation is rarely required for patients with isolated flail chest injuries. When early intubation is indicated, it is usually for associated injuries, most commonly to the central nervous system (CNS).

In virtually all awake and alert patients, management without intubation should be attempted. To this end, early and aggressive pain management is essential. Pain cannot be eliminated entirely, but it usually can be diminished sufficiently to allow an adequate tidal volume and a forceful cough. Oral analgesics rarely suffice for patients with even a small flail segment; stronger agents are required for all but the most stoic of patients. Parenteral narcotics are effective, especially when administered in a patient-controlled analgesia (PCA) device. Intercostal nerve blocks occasionally provide dramatic pain relief, but only for short periods. If the patient is encouraged to cough vigorously during pain relief, intermittent nerve blocks may be helpful, despite the inherent risk of pneumothorax.

The mainstay of pain control in patients with flail chest is thoracic epidural anesthesia, in which a solution containing 0.002 to 0.005% morphine sulfate and 0.075 to 0.2% bupivacaine is infused through a small catheter in the thoracic epidural space at a constant rate of 0.15 to 0.75 mg morphine/hr. At this low dosage, bupivacaine acts synergistically with morphine and does not exert a local anesthetic effect on the spinal cord; in addition, it generally does not give rise to the respiratory depression frequently observed with systemic narcotics. Epidural anesthesia provides immediate comfort, dramatically improves vital capacity and tidal volume, and, most important, enables the patient to produce a forceful cough.³³

The most common serious adverse effect of epidural anesthesia is transient hypotension at the time of insertion. This complication can be prevented by providing adequate volume resuscitation before creating the chemical sympathectomy. Urinary retention occurs in 30 to 50% of cases; in practical terms, this means that most flail chest patients should not have their urinary catheters removed until the epidural analgesics are no longer required. Patients who have head injuries and are thus at risk for increased intracranial pressure should not undergo epidural catheterization, because an unintentional dural puncture could alter cerebrospinal pressure sufficiently to induce or contribute to cerebral herniation. Relative contraindications to epidural catheter placement include spine fractures and infection; however, fever may be a relative indication if it is thought to be secondary to splinting with atelectasis or pneumonia.

The decision-making process for management of flail chest should begin with assessment of the patient's ability to cough [see Figure 3]. If the patient is able to clear tracheal secretions—that is, actually cough them up into the oropharynx—then observation in an acute care setting, in conjunction with small, infrequent doses of narcotics, is appropriate. If the patient has no cough or has a very truncated cough that moves secretions but does not propel them into the oropharynx, an aggressive program to promote pulmonary toilet should be instituted. If a sufficiently vigorous cough cannot be achieved and there is no specific contraindication, an epidural catheter is inserted and the patient is followed closely with frequent physical examinations in the intensive care unit. Ambulation is encouraged, and frequent coughing is required. It is important that management decisions be made early and followed closely so that effective therapy can be started expeditiously. There is no role for antibiotic prophylaxis or steroid use in the management of patients with flail chest or pulmonary contusion.

Figure 3 Algorithm illustrating approach to the management of flail chest.

Depending on the presence and severity of an underlying pulmonary contusion and adequate pulmonary toilet, many flail chest victims can avoid intubation.³⁴ However, any patient with flail chest who demonstrates further deterioration of pulmonary function and who becomes hypoxic or hypercarbic should undergo mechanical ventilation aimed at (1) ensuring a tidal volume adequate for establishing normal chest wall excursion and (2) maintaining a respiratory rate adequate for achieving normocarbica. Hypoxia is managed by increasing the fraction of inspired oxygen (FiO₂) and applying sufficient positive end-expiratory pressure to achieve adequate oxygenation (usually defined as arterial oxygen saturation greater than 90%) with nontoxic levels of FiO₂.

A few patients with severe disruption of chest wall mechanics as a result of flail chest continue to require positive pressure ventilation even though adequate pain control has been achieved and the pulmonary contusions are beginning to resolve. Some of them may benefit from internal fixation of the multiple rib fractures, which restores chest wall stability and eliminates much of the fracture-related pain. A variety of methods have been described to stabilize the ribs and obtain compression osteosynthesis of each fracture site. An isolated, single-institution series described the efficacy of this procedure in patients with flail chest.^{35,36} Further clinical trials are needed.

PENETRATING

In most cases of penetrating thoracic trauma, the injury to the chest wall is vastly overshadowed by the injury, or potential for injury, to the intrathoracic structures. The notable exceptions to this general rule are hemorrhage and open chest wounds.

Hemorrhage

Stab wounds and low-caliber gunshot wounds to the anterior chest are common in urban areas. Once serious injury to intrathoracic organs has been excluded, such injuries often can be managed with tube thoracostomy or observation alone. Indications for urgent thoracotomy are discussed elsewhere [see Operative Considerations, Indications for Operative Management, *above*].

In patients with persistent hemorrhage from chest tubes who require thoracotomy, the most common source of the bleeding is a lacerated internal mammary or intercostal artery. Attempts to control bleeding from these vessels nonoperatively usually fail. Angiography to localize the bleeding vessel is unnecessary and delays definitive care: coupled with embolization of the lacerated vessel, it is more time consuming than surgical intervention and does not address associated injuries and hemothorax.

Penetrating wounds to the midportion of the pectoral muscle occur with surprising frequency, possibly as a result of an assailant's erroneous conception of the location of the heart. Such injuries often lacerate the pectoral branch of the thoracoacromial artery, which courses along the posterior surface of the pectoral muscle. Control of this troublesome bleeding is extremely difficult to achieve if exploration is attempted directly through an extension of the entrance wound, but exposure is much improved if exploration is attempted through an oblique wound along the lateral pectoral margin after entry into the subpectoral plane.

Open Chest Wounds

The diagnosis of an open chest wound is usually obvious, and their treatment depends on the size of the wound and the size of the chest wall defect. Most small open pneumothoraces can be managed initially with occlusive dressings, but there is usually an underlying pulmonary injury with air leakage, which necessitates early tube thoracostomy to prevent tension pneumothorax. Once the patient's condition is stable, the wound can be debrided and closed. Occasionally, primary skin closure must be delayed.

Larger chest wall defects pose a challenging therapeutic problem. Such wounds usually result from high-velocity missiles or shotguns fired at close range. Initial management is directed toward restoration of respiratory mechanics with early intubation and mechanical ventilation.

The next priority is to address any underlying intrathoracic injuries, which may range from mild pulmonary contusion to massive hemorrhage in conjunction with severe lung or hollow viscus injury. When associated intrathoracic injuries are present, the first step in the closure of the defect is to select an appropriate operative approach. Although the primary objective in this situation is to provide excellent exposure for repair of what may be life-threatening injuries, whenever possible, the thoracotomy should be performed in such a way as to preserve the blood supply and muscle mass of the chest wall adjacent to the defect.

After definitive repair of intrathoracic injuries and débridement of devitalized chest wall tissue, the next step is to plan the closure. Such planning requires a degree of familiarity with current and developing techniques and an understanding of pleural drainage, respiratory mechanics, and techniques of tissue transfer. Collaboration with plastic and thoracic surgeons is often helpful. Most chest wall defects can be closed with viable autogenous tissue, usually through rotation of local myocutaneous or myofascial flaps of the pectoral muscle, the latissimus dorsi, or the rectus abdominis.

Pulmonary Injuries

Because of their size, the lungs are commonly injured in cases of thoracic trauma. Mortality from pulmonary lacerations is directly proportional to the amount of blood lost. A 1,500 mL hemothorax, regardless of causative mechanism, should always prompt exploration.

LACERATIONS

Bleeding pulmonary lacerations can be oversewn, resected, or explored via pulmonary tractotomy. Bleeding from small or shallow lacerations can be controlled with an over-and-over repair using a continuous monofilament suture. Bleeding from deeper lacerations is controlled with resection or tractotomy. Most pulmonary resections for trauma should be stapled, nonanatomic resections; however, anatomic lung resection is required in rare instances, and trauma surgeons should remain familiar with the technical aspects of this procedure.³⁷ Mortality is proportional to the amount of lung tissue resected: with suture repair alone, mortality is 9%; with tractotomy, 13%; with wedge resection, 30%; with lobectomy, 43%; and with pneumonectomy, 50%.^{38,39}

Tractotomy is especially useful for deep through-and-through injuries that do not involve the hilum.⁴⁰ In this

technique, the injury tract is opened with a linear stapler [see Figure 4] or between two aortic clamps. If clamps are used, the cut lung edges are oversewn and the tract left open. Tractotomy exposes bleeding vessels and air leaks inside the tract and permits selective ligation. Occasionally, it exposes an injury to a major vascular or airway structure that must be treated with a formal resection. Because of the risk of exsanguination or excessive devitalization of lung tissue, tractotomy is not indicated when the injury traverses the hilum or when the entire thickness of a lobe will be cut.

Central lung injuries often cause massive hemorrhage. In addition, they may be sources of pulmonary venous air emboli when both a major pulmonary vein and a large airway are disrupted. A common scenario involves an intubated patient who exhibits sudden deterioration of CNS and cardiac status shortly after being placed on positive pressure ventilation. Emergency thoracotomy must be performed and the pulmonary hilum clamped or twisted. The diagnosis is confirmed by visualizing air in the epicardial coronary arteries. Aspiration of air from the left-side cardiac chambers and elevation of central blood pressure are also useful maneuvers. Most central lung injuries are associated with extensive parenchymal injury in gravely ill patients. Selective repair of hilar structures is usually impractical in this setting, and lobectomy or pneumonectomy is the salvage procedure of choice.

CONTUSIONS

Pulmonary contusions are bruises to the lung that usually are caused by blunt trauma to the chest but sometimes result from penetrating injury by high-velocity weapons. The contused segment of the lung has a profound ventilation-perfusion mismatch, which produces an intrapulmonary right-to-left shunt and hypoxia. The clinical sequelae of lung contusion may vary from simple shortness of breath to respiratory failure requiring mechanical ventilation. There is systemic activation of the innate immune system as a result of lung contusion as evidenced by the local and systemic production of various inflammatory mediators such as the interleukins, prostaglandins, and chemokines. This resultant

inflammatory response contributes to the evolution of pulmonary and remote organ dysfunction.⁴¹ Typically, the bruise is not fully appreciated on a chest x-ray, but it is fully evident on a chest CT scan [see Figure 5]. In fact, the size of the contusion as measured on a chest CT scan is directly proportional to the risk of developing posttraumatic acute respiratory distress syndrome (ARDS).⁴² Lung contusion is a well-established risk factor for pneumonia, and the bruised lung also may serve later as a source of sepsis.

Most pulmonary contusions that are not complicated by excessive attempts at resuscitation or by superinfection resolve over 3 to 5 days. Supportive care in the form of cardiovascular and, if necessary, ventilatory support must be provided. In general, pulmonary contusion is treated in much the same fashion as flail chest. Patients with rib fractures and painful chest wall excursions must be given sufficient analgesic support to allow them to produce a cough forceful enough to maintain pulmonary toilet. Intubated patients should undergo suctioning frequently. Patients with pulmonary contusions who require substantial volume resuscitation should be considered for pulmonary arterial catheter monitoring. Steroids are not indicated, because they have no effect on the development or resolution of the contusion and because they set the stage for subsequent infection. Diuretics and prophylactic antibiotics are also unnecessary.

Figure 4 Pulmonary tractotomy is useful for controlling hemorrhage associated with deep through-and-through injuries to the lungs.

Figure 5 Chest computed tomographic scan of a pulmonary contusion with three-dimensional reconstruction.

Tracheobronchial Injuries

Although tracheobronchial injuries are rare and often lethal, a high index of suspicion for the existence of the injury, a timely diagnosis, and appropriate intervention can improve the chances of a successful outcome. The reported incidence of tracheobronchial injury in blunt chest trauma patients ranges from 0.2 to 8%.^{43–45} Concomitant injury is the rule rather than the exception, but the patterns of associated injury vary widely.⁴⁶ More than 80% of tracheobronchial ruptures occur within 2.5 cm of the carina. Mainstem bronchi are injured in 86% of patients and distal bronchi in only 9.3%, whereas complex injuries are seen in 8%.

Various clinical presentations result after injury to the tracheobronchial tree, generally depending on the severity and the location of the injury. In the neck, airway involvement may create severe respiratory distress that causes death before emergency care can be given. Alternatively, patients with cervical tracheal injuries may present with stridor and severe respiratory distress or with hoarseness, hemoptysis, or cervical subcutaneous emphysema.

The presentation of thoracic tracheobronchial injury depends on whether the injury is confined to the mediastinum or communicates with the pleural space. Thoracic tracheobronchial injuries confined to the mediastinum usually present with a massive pneumomediastinum. Injuries that do extend into the pleural space usually create an ipsilateral pneumothorax that may or may not be under tension. A pneumothorax that persists despite adequate placement of a thoracostomy tube and that leaks air continuously is suggestive of tracheobronchial injury and bronchopleural fistula. Dyspnea may actually worsen after insertion of the chest tube because of the loss of tidal volume via the tube. Several radiographic clues to possible airway injury may be observed with endotracheal intubation, such as abnormal migration of the tube tip and distention of the endotracheal tube balloon beyond the normal tracheal diameter.

In only 30% of cases is a definitive diagnosis of tracheobronchial injury made within 24 hours. More often, the diagnosis is made late, when pulmonary collapse distal to the injury and sepsis occur. As many as 10% of tracheobronchial tears give rise to no initial clinical or radiologic signs and are not recognized until months later, after stricture occurs. Immediate intubation of patients with multisystem trauma can mask laryngeal or high cervical tracheal injuries and thereby delay the diagnosis. After tracheobronchial transection, the peribronchial connective tissues sometimes remain intact and allow continued ventilation of the distal lung in much the same way that perfusion is maintained after traumatic aortic transection. If unrecognized, this injury heals with scarring and granulation tissue and occasionally creates bronchial obstruction.

The diagnosis is typically suspected on the basis of the clinical history and the characteristic signs and symptoms [see Figure 6]. The advent of spiral CT with multiplanar reconstruction has led to renewed interest in the use of this modality to evaluate tracheobronchial injury. An increasing number of reports demonstrate the utility of CT technology in diagnosing tracheobronchial injuries, with a sensitivity approaching 100%.^{47,48} Thus, because of its excellent negative

predictive value, CT may be employed as a screening tool to look for these injuries in stable patients; however, at present, diagnostic bronchoscopy remains necessary to reliably exclude the diagnosis of tracheobronchial injury. In stable patients with transmediastinal gunshot wounds, chest CT may be used to detect the proximity of the missile tract to mediastinal structures, directing subsequent evaluation.²³ Indications for bronchoscopy in this setting include a large pneumomediastinum, a refractory pneumothorax, a large air leak, persistent atelectasis, and possibly marked subcutaneous emphysema.⁴⁶

Bronchoscopy, either rigid or flexible, is the most reliable means of establishing the diagnosis and determining the site, nature, and extent of the tracheobronchial disruption. Whichever type of scope is used, the signs and symptoms should be correlated with the endoscopic findings. The most critical determinant seems to be the endoscopist's level of experience and comfort with the procedure. An experienced bronchoscopist can perform either technique with a high degree of sensitivity, specificity, and accuracy.⁴⁴ Often the lesions are missed initially, or their severity is underestimated, or they evolve into more obvious or severe lesions. For this reason, bronchoscopy should be liberally repeated as needed.

MANAGEMENT

With tracheobronchial injuries, as with all injuries, airway management is the first priority in treatment. If the patient is maintaining his or her own airway and is adequately ventilated, a cautious noninterventional approach is probably the best initial choice until further diagnostic workup is performed or other life-threatening injuries are stabilized. Careless handling or mishandling of the airway (e.g., inadvertently placing an endotracheal tube through a transected or ruptured airway and into soft tissue) can be disastrous and may compound the injury. ED tracheostomies are difficult and may be dangerous, to say the least.

How best to secure an airway in a patient with neck trauma and possible tracheal injury is a matter of debate. With blind endotracheal intubation, the path of the tube distal to the larynx is unknown, and it is possible to lose the lumen or create a false passage. With intubation over a flexible bronchoscope, the tube can be visualized as it passes beyond the site of injury, and some of the dangers of blind intubation are thereby mitigated; however, some degree of sedation is usually required, and if the patient is oversedated, the airway that was being spontaneously protected may be lost. Paralytic medications should generally be avoided in this setting, for the same reason. Urgent tracheostomy or cricothyrotomy, performed in the OR, is advocated by many as the safest and securest way of obtaining airway control. If the trachea is completely transected, the distal trachea can usually be found in the superior mediastinum and grasped for insertion of a cuffed tube. The approach taken to airway control must vary with the resources and expertise available at each institution. One must also keep in mind that even after the airway is secured, it may still be possible to exacerbate the injury by means of aggressive ventilation with high airway pressures. Tube thoracostomies should be appropriately placed at this time and connected to suction, even though dyspnea may worsen.

Figure 6 Algorithm illustrating approach to management of suspected tracheobronchial injury. PPI = proton pump inhibitor.

Once the airway is controlled, there is time for orderly identification of concurrent injuries, esophagoscopy, laryngoscopy, arteriography, transport to definitive care areas, and, if necessary, celiotomy.

Nonoperative

On occasion, asymptomatic tracheobronchial tears are found incidentally in the course of bronchoscopy or other imaging procedures. Nonoperative management is reserved for highly selected patients with unsuspected small injuries of this type. Lesions suitable for observation must involve less than one third of the circumference of the tracheobronchial tree. For patients to be candidates for nonoperative care,

their lungs should be fully reexpanded with tube thoracostomy, and any air leaks should stop soon after insertion of the tube. There must be no associated injuries and no need for positive pressure ventilation. Prophylactic antibiotics, humidified oxygen, voice rest, frequent suctioning, and close observation for sepsis and airway obstruction are required.

Small penetrating wounds with well-opposed edges and no evidence of loss or devitalization of tracheal tissue may be effectively treated with temporary endotracheal intubation.⁴⁹ The cuff of the endotracheal tube should be inflated below the level of injury and left undisturbed for 24 to 48 hours while the wound seals. If a conservatively managed patient's clinical condition deteriorates, bronchoscopy should be

liberally repeated. Even small tears may produce substantial amounts of granulation tissue on healing, which may necessitate late endobronchial excision.

Operative

Like emergency airway management, intraoperative airway management requires close coordination with the anesthesiologist. After the airway is initially secured, manipulation during the repair creates additional challenges. A sterile anesthesia circuit and tube must be available to pass off the table once control of the airway at the level of transection has been regained. In especially difficult cases, in which airway management is unsatisfactory or the repair is complex, cardiopulmonary bypass or venovenous extracorporeal membrane oxygenation (ECMO) may be instituted. Both techniques require systemic anticoagulation, and their potential risks and benefits in multiply injured patients remain to be determined. Once the repair is complete, the endotracheal tube ideally should be removed immediately after the operation.

Intrathoracic tracheal, right bronchial, and proximal left mainstem bronchus injuries are best repaired through a right posterolateral thoracotomy at the fourth or fifth intercostal space because this approach is blocked from the left by the heart and the aortic arch. Complex or bilateral injuries are also approached through the right chest, for the same reason. Distal left bronchial injuries more than 3 cm from the carina are approached through a left posterolateral thoracotomy in the fifth intercostal space.

Optimal repair includes adequate débridement of devitalized tissue (including cartilage) and primary end-to-end anastomosis of the clean tracheal or bronchial ends [see Figure 7]. The anastomosis can be accomplished without tension by mobilizing the structures anteriorly and posteriorly, thereby preserving the lateral blood supply. On occasion, bronchial sleeve resection, lobectomy, or pneumonectomy is urgently

required for more extensive or distal injuries to lobar or segmental bronchi.

Esophageal Injuries

Injury to the esophagus, although relatively rare, poses particular problems for the treating physician because of the complexity of the presentation, the workup, and the treatment options. Despite diagnostic and therapeutic advances, the morbidity and mortality associated with esophageal injury remain high. Preoperative evaluation is still a subject of debate, as is the question of mandatory surgical exploration versus selective nonoperative management. Currently, most esophageal injuries are iatrogenic or endoluminal; however, we will concentrate here on injuries specifically related to external trauma—namely, penetrating injury and blunt esophageal rupture.

Whereas the cervical esophagus is relatively unprotected from external trauma, the thoracic esophagus, being surrounded by the bony thorax, is well protected. The esophagus lies in close proximity to the heart, the great vessels, and the entire membranous portion of the trachea. Consequently, simultaneous injury to several of these intrathoracic organs is common, which greatly increases associated morbidity and mortality. The esophagus has no serosal covering; rather, it is entirely surrounded by loose areolar connective tissue, which makes suture placement less secure and increases the overall difficulty of surgical repair. **The planes of the paraesophageal and prevertebral spaces communicate freely with the mediastinum. As a result, spillage from the esophagus readily tracks into the mediastinum, leading to mediastinitis, causing sepsis, and accounting for much of the increased morbidity and mortality seen with delayed diagnosis and treatment of esophageal injuries.**

Figure 7 Tracheal injury may be repaired by means of segmental resection, with the suture line buttressed with an intercostal muscle flap.

SCORE Most esophageal injuries result from penetrating trauma. If surgical exploration is performed for all penetrating cervical wounds that violate the platysma, the esophagus is found to be injured approximately 12% of the time. Penetrating intrathoracic esophageal injuries are less common, however, occurring in about 0.7% of all penetrating chest wounds.⁵⁰ Blunt esophageal trauma is relatively uncommon, tending to occur just proximal to the esophagogastric junction on the left side, where the esophagus is less well protected.

SCORE Between 60 and 80% of esophageal injuries give rise to clinical signs or symptoms, the sensitivity and specificity of which depend on the location of the injury, the size of the perforation, the degree of contamination, the length of time elapsed after injury, and the presence of associated injury. Odynophagia, dysphagia, hematemesis, oropharyngeal blood, cervical crepitus, pain and tenderness in the neck or chest, resistance to passive motion, dyspnea, hoarseness, bleeding, cough, and stridor are commonly noted. Fever, subcutaneous emphysema, abdominal tenderness, and mediastinal crunching sounds (Hamman sign) may be observed. Pain is the most common presenting symptom (71% of patients), followed by fever (51%), dyspnea (24%), and crepitus (22%).⁵¹ Overall, the signs and symptoms associated with esophageal injury are fairly nonspecific, and a high index of suspicion must be maintained to make the diagnosis.

SCORE Evaluation of potential penetrating trauma to the esophagus is based on the trajectory and path of the missile. For penetrating injuries near the organ, it is necessary to prove that the esophagus is uninjured. Generally, this is done in one of two ways: (1) surgical exploration demonstrates a missile path inconsistent with esophageal injury or (2) direct examination of the esophagus reveals no injury. If neither option is feasible, proof is obtained through diagnostic testing. Plain x-rays, CT scans, and contrast esophagograms have all been used for this purpose, with varying sensitivity and specificity [see Table 2]. Endoscopy may add to the diagnosis, but the results depend on the operator's technique and experience, and there is a risk that it may exacerbate an esophageal tear or further injure an unstable cervical spine.

In an otherwise asymptomatic patient who is awake, alert, and able to cooperate, a simple contrast swallow is usually sufficient to exclude injury. Injuries resulting from low-velocity projectiles and stab wounds do not cause large tissue defects; for these injuries, barium gives superior anatomic detail and is the agent of choice. Injuries from large-caliber or high-velocity projectiles usually cause more damage; thus, the contrast agent tends to spread more widely throughout

the mediastinum during a diagnostic swallow. If contrast studies are indicated in this setting, a water-soluble agent may be used first. Such agents cause pulmonary damage when aspirated, however, and should not be used if tracheo-esophageal fistula is suspected.

For patients who are going to the OR for another reason (e.g., vascular repair or laparotomy), it may be most expedient to perform esophagoscopy simultaneously with the operation. If the entire esophagus is well visualized and no injury is identified, no further evaluation is required. If the study is suboptimal for any reason, or if the possibility of an injury persists, a contrast study should be done as soon as the patient's condition permits.

Regardless of the diagnostic studies obtained, evaluation must be carried out expeditiously. Significant delays in management can increase the incidence of esophageal injury-related morbidity by as much as a factor of two.⁵²

In cases of blunt trauma, determining when further study is needed is a vexing task. In general, whenever a patient has pneumomediastinum that is extensive or is associated with any of the symptoms of esophageal injury (e.g., odynophagia or blood in the esophagus), the esophagus should be evaluated. Simple pneumomediastinum rarely warrants evaluation of the esophagus. Chest CT may also be useful in delineating who needs further workup as it identifies patients with high risk of aerodigestive injury.⁵³ In the absence of suggestive signs, symptoms, and radiographic findings, pneumomediastinum associated with blunt trauma is much more likely to be from a distal small airway disruption or from a bronchial injury, the evaluation of which should take precedence over evaluation of the esophagus.

MANAGEMENT

Although injuries to the thoracic esophagus caused by external trauma are less common than those to the cervical esophagus, they are more likely to be fatal.⁵⁰ Trauma to the thoracic esophagus is almost exclusively caused by gunshot wounds; the location of the organ within the chest protects it from most stab wounds. Care of any associated injuries to surrounding structures (e.g., major airways and blood vessels) takes precedence in the management scheme; thus, by necessity, diagnosis and definitive therapy of intrathoracic esophageal injuries are often delayed. Guidelines have been formulated for the evaluation of transmediastinal penetrating wounds [see Figure 8].

SCORE Injuries to the distal third of the thoracic esophagus are most easily approached via the left chest. More proximal injuries are best approached through the right chest or via a combination of chest and cervical incisions. The incision should be made so as to facilitate subsequent buttressing of the repair (e.g., with a pedicle from an intercostal muscle or the latissimus dorsi).

Surgical repair entails local débridement, wide drainage, primary repair of the perforation, and buttressing of the repair with a viable muscle flap. Primary repair can usually be accomplished when the perforation is operated on within 24 hours of occurrence. Many investigators recommend two-layer repair of esophageal injuries; however, a secure single-layer repair performed with a continuous absorbable monofilament suture (e.g., 3-0 polydioxanone) allows excellent visualization of each bite and good mucosa-to-mucosa

Table 2 Diagnostic Measures for Evaluating Suspected Esophageal Injuries

Diagnostic Measure	Sensitivity (%)	Specificity (%)	Accuracy (%)
Assessment of clinical signs and symptoms	80	64	72
Contrast esophagography	80–100	94–100	90–95
Rigid esophagoscopy	67–100	89–95	86–94
Flexible esophagoscopy	67–100	67–100	82–97

Figure 8 Algorithm illustrating approach to management of transmediastinal penetrating injury. CT = computed tomographic; OR = operating room.

approximation. A number of different tissue flaps—free pericardium, pleura, intercostal muscle, diaphragm, rhomboid muscle, lung, and gastric fundus (as in a Thal patch)—have all been used, with varying success. Placement of a gastrostomy tube for gastric drainage and jejunal feeding tube for enteral feeding access should be considered in all of these patients.

Depending on the interval before exploration, the severity of the injury, the degree of contamination, and the extent of the local inflammatory response, primary repair may not be feasible, although an attempt at primary repair with autologous tissue coverage is recommended. If this is the case, several techniques may be employed, including esophageal diversion, total esophageal exclusion, esophagectomy, and T tube drainage. Most of the experience with these delayed repairs has been acquired in patients who have perforations

caused by instrumentation or by iatrogenic esophageal rupture, neither of which is entirely analogous to the injuries seen with external trauma.

In the absence of distal obstruction, almost all late-presenting esophageal perforations heal after primary repair and tissue flap coverage. Generally speaking, techniques such as esophageal exclusion, diversion, and resection should be needed only when perforation occurs in the setting of a primary esophageal pathologic condition (e.g., cancer); esophageal perforation in this setting is rarely managed by trauma surgeons.

Complications

Complications seen after esophageal repair include esophageal leakage and fistula, wound infection, mediastinitis, empyema, sepsis, and pneumonia. Long-term complications

(e.g., esophageal stricture) also occur, but they are more common after iatrogenic perforation of an already diseased esophagus.

Esophageal anastomotic leakage is the most common complication associated with repair of perforations, occurring in 10 to 28% of repairs.⁵⁴ The causes are primarily technical and include inadequate débridement, devascularization, closure under tension, and the presence of associated infection. As many as 50% of these leaks are asymptomatic; in this setting, they are usually associated with prompt flow of oral contrast back into the esophageal or gastric lumen. Continued abstinence from oral intake, supplemental nutrition, and antibiotic therapy usually suffice for successful treatment.

In patients who have sepsis and esophageal leakage after repair of an esophageal perforation caused by external trauma, treatment should focus on wide local drainage and creation of a controlled fistula, which is usually best accomplished by resecting a segment of a rib posteriorly at the level of the perforation and then packing the wound open. Because there is usually no underlying esophageal or gastric pathologic condition and no forceful distribution of mediastinal contamination, these fistulas generally heal well without resection, diversion, or replacement of the esophagus.

Thoracic Duct Injuries

Chylothorax after blunt or penetrating chest trauma is rare; only case reports and small case series are found in the literature. Much of the management of this condition is extrapolated from management of iatrogenic thoracic duct injuries, which are much more common. Most patients with traumatic chylothorax show evidence of other axial injuries to the chest, especially spine fractures.⁵⁵ The diagnosis is made by finding chylomicrons and high levels of triglycerides in a typically large pleural effusion of milky appearance. Drainage of as much as 1,000 mL/day is not unusual and results in severe nutritional and immunologic derangements, which are the main causes of the high mortality associated with this condition.

MANAGEMENT

Treatment usually begins with limiting oral intake of short- and long-chain triglycerides, which cause increased flow of chyle. Diets high in medium-chain triglycerides must often be given enterally because they are not palatable. Some clinicians recommend instituting total parenteral nutrition with complete abstinence from oral intake. Administration of octreotide may also help decrease chyle production.⁵⁶ These modalities, in conjunction with adequate pleural drainage and lung expansion, are successful in approximately 50% of cases after 2 to 6 weeks.

Operative strategies for managing thoracic duct injuries are generally undertaken only after conservative measures fail. Preoperatively, patients are fed cream, with or without dyes such as Sudan black, to increase chyle flow and enhance visualization of the site of injury. The thoracic duct is then ligated above and below the injury; this may be performed by means of VATS on the hemithorax ipsilateral to the effusion.⁵⁷ Fibrin glue and talc pleurodesis may be used as adjuncts to ligation. Because there are usually multiple areas

of injury and because the thoracic duct is friable by nature, surgical treatment is not always successful. Continued nutritional management and reoperation may be required.

Cardiac Injuries

The incidence of cardiac trauma continues to rise as a consequence of growing urban violence, improved detection of cardiac injuries, and an increase in the percentage of patients with such injuries who arrive at trauma centers alive. Improved prehospital transport, along with the continuing evolution of diagnostic, surgical, and anesthetic techniques, has contributed to an increase in overall survival in this population. Although the overall mortality associated with cardiac trauma remains high, survival rates of 50 to 95% are not uncommon in patients who arrive at the hospital with vital signs.^{58–60}

PENETRATING

Patients with penetrating cardiac injuries generally present in one of three ways. In approximately 20% of patients, the injury is clinically silent, at least initially, and is subsequently diagnosed at operation or on diagnostic imaging. In approximately 50%, there is evidence of pericardial tamponade, including one or more of the signs in the Beck triad (hypotension, distended neck veins, and muffled heart sounds). In the remaining patients, hemorrhagic shock develops after free bleeding from an atrial or ventricular wound into one or both hemithoraces.

Diagnosis of penetrating injuries to the heart often requires a high index of suspicion. The locations of entrance and exit wounds, the trajectory and path of the wounding object, and the locations of any retained missiles on radiographs are helpful in predicting heart injuries. Proximity wounds to the heart are defined as those that penetrate the chest wall in the area bounded superiorly by the clavicles, laterally by the midclavicular lines, and inferiorly by the costal margins. Any crossing of the anterior mediastinum by a missile or an instrument is also considered a proximity wound. Because cardiac injuries are present in 15 to 20% of patients who present with proximity wounds, these injuries must be definitively excluded.

Physical examination is often unreliable in detecting pericardial tamponade. It is rare for all three signs in the Beck triad to be found; in fact, only about half of patients with tamponade show even two of the three. Moreover, detection of muffled heart sounds and distended neck veins amid the commotion typical of the trauma bay can be extremely difficult, especially when (as is often the case) the patient is agitated or intoxicated. Accordingly, whenever tamponade is suspected, additional diagnostic modalities should be employed.

As more surgeons become familiar with the use of ultrasonography in the trauma setting, two-dimensional surface echocardiography is gaining acceptance as a means of diagnosing cardiac injuries. When performed by appropriately trained surgeons, this modality detects blood within the pericardial sac with a sensitivity of 96 to 100% and a specificity of 100%—results essentially equivalent to those achieved with a pericardial window.⁶¹ However, the sensitivity of echocardiography for detecting cardiac injuries is diminished in

the presence of a hemothorax; thus, when clinic suspicion of a cardiac injury is present in conjunction with a hemothorax in a stable patient, alternative diagnostic modalities should be considered (pericardial window). When the requisite equipment is readily available, this test can be performed in approximately 2 minutes. It is of vital importance that the trauma surgeon who is attending to the patient performs and interprets the test: the results will be available sooner, the clinical correlation will be more accurate, and the information obtained will be more rapidly applied to treatment decisions. The main limitations of two-dimensional surface echocardiography are the high cost of the equipment and the specialized training required.

Although cardiac ultrasonography has many advantages, the subxiphoid pericardial window remains the gold standard for diagnosis of cardiac injury. For otherwise stable patients with proximity wounds or suggestive signs and symptoms, a pericardial window should be considered when ultrasonographic findings are equivocal or when ultrasonography is unavailable. This procedure is usually performed in the OR with the patient under general anesthesia, often in combination with abdominal exploration.

A subxiphoid pericardial window is performed through a 10 cm vertical midline incision that is made over the xiphoid, slightly favoring the epigastrium. The xiphoid is grasped with a clamp and dissected away from the abdominal fascia and the diaphragmatic fibers, and the substernal plane is accessed. As the inferior portion of the sternum is being elevated, the prepericardial adipose tissue is dissected to provide exposure of the acute margin of the pericardium. The pericardium is then retracted inferiorly into the wound and incised sharply. The presence of blood or clot within the pericardial sac indicates a positive result, necessitating immediate repair of the injury. A pericardial window can also be accomplished during thoracoscopy of the left hemithorax, and examination of the pericardium can be performed, although less reliably, during laparoscopy via a transdiaphragmatic view.

Some authorities advocate using pericardiocentesis to detect cardiac injuries, especially where rapid access to the OR, trauma surgeons, and anesthesiologists is not available. Drawbacks to this approach include the high rate of false positives and false negatives and the potential for iatrogenic cardiac injuries. Furthermore, pericardiocentesis is of limited use in treating tamponade because blood within the pericardial sac often is clotted and is not amenable to removal through a needle.

Management

Treatment of penetrating cardiac wounds depends on the urgency of the presentation. In patients who are in shock from suspected cardiac injuries, the distinction between the two most likely causes, pericardial tamponade and free hemorrhage, is important. If the patient exhibits distended neck veins and the characteristic plethoric, dusky facial expression, chest tubes should immediately be placed bilaterally. If shock does not then resolve, the diagnosis of tamponade should be made and a pericardial window performed, either in the ED with local or no anesthesia or in the OR as described (see above). If there is a suspicion of free hemorrhage into one or both hemithoraces, which can usually be detected by means of physical examination and chest x-ray, the patient should

be transported to the OR for definitive treatment. In patients who are in extremis from either causative condition or who go into cardiac arrest in the ED, an emergency left anterior thoracotomy should be performed.

In planning the surgical approach to the repair of cardiac injuries, the location of the entrance and exit wounds, the path of the wounding object, the type of wound created, the associated signs and symptoms, and the level of suspicion for other thoracic visceral injuries are important considerations. A median sternotomy is a logical extension of a subxiphoid pericardial window and provides access to all four chambers of the heart. It is appropriate for most precordial stab wounds and some low-caliber gunshot wounds. Its main limitations are that it does not allow repair or cross-clamping of the descending aorta or examination or repair of the esophagus and bronchi and that it provides limited exposure of the lower lobes of the lungs and the hemidiaphragms. A left thoracotomy is appropriate for patients who may require cross-clamping of the thoracic aorta and for those with suspected cardiac injuries in conjunction with other complex thoracic visceral injuries. Only occasionally is a right thoracotomy required; this incision generally does not provide adequate exposure of the heart.

Atrial wounds are generally amenable to early control by finger pressure or by exclusion with a vascular clamp and simple oversewing. Right or left ventricular free wall injuries away from the coronary arteries may be treated by applying digital pressure over the entrance wound for hemostasis and then placing horizontal mattress sutures under the wound, reinforced with an epicardial continuous suture along the site of injury. All left ventricular wounds should be repaired with felt-pledgeted or pericardial-pledgeted sutures. Many right ventricular stab wounds can be closed primarily without pledgets if the sutures are tied accurately.

Injuries near coronary arteries must be closed without the coronary artery being incorporated within the suture. This can be accomplished by placing horizontal mattress sutures lateral and deep to the coronary artery across the cardiac laceration. If the sutures are tied with careful attention to the function of the myocardium distal to the injury and equally careful attention to the ECG, the laceration can be closed without coronary artery occlusion and subsequent ischemia.

An alternative method of repair of cardiac lacerations employs a skin stapler, which is effective in controlling hemorrhage from stab injuries and low-velocity gunshot wounds.⁶² The stapler can be used on all chambers of the heart, and in some instances, staple repair can be quicker than suture repair.

With all penetrating cardiac wounds, it is important to recognize the possibility of associated intracardiac injuries. The surgeon should palpate the heart along the pulmonary outflow tract for a thrill that would indicate a traumatic ventricular septal defect. This diagnosis can be confirmed by performing co-oximetry on a sample of blood aspirated from the pulmonary artery and the right atrium and demonstrating a step-up. Digital palpation through atrial wounds should be routinely employed to identify atrioventricular valvular insufficiency or, occasionally, an atrial septal defect. Intraoperative surface echocardiography and transesophageal echocardiography are also excellent at diagnosing intracardiac injuries, but they are not readily available in the urgent trauma setting.

Postoperatively, all patients with cardiac wounds should receive a thorough cardiovascular examination aimed at detecting murmurs or evidence of cardiac failure and should undergo echocardiography if either of these is detected. Repair of intracardiac lesions usually can wait until the patient's condition is stable and cardiac catheterization has been performed, although some patients experience such profound heart failure that immediate operative repair, with cardiopulmonary bypass, must be performed.

BLUNT

Blunt cardiac injuries range from disruption of myocardium, septa, or valvular structures to cardiac contusion. Both cardiac disruption (also known as cardiorrhexia) and cardiac contusion are common; the former is seen most often in patients who die at the scene and the latter in those who survive to reach the hospital.

Blunt cardiac injury typically involves a direct blow to the chest, usually sustained in a motor vehicle collision or a fall. Cardiac injuries generally are associated with sternal or rib fractures, although they may occur in the absence of any chest wall fracture; however, sternal fractures do not predict the presence of blunt cardiac injury. The most common location of blunt cardiac injury is the anterior heart, which consists primarily of the right ventricle. A blow that causes the sternum to exert a direct impact on the myocardium may result in direct injury to myocardial cells, sometimes leading to cell death, mechanical dysfunction, or dysrhythmias.

The diagnosis of myocardial contusion is elusive. Many tests have been proposed, but none have proved definitive, except for direct visualization of the heart at surgery or autopsy. For practical purposes, the clinically significant sequelae of myocardial contusion are myocardial dysrhythmias and pump failure. Both of these sequelae must be treated, regardless of whether the diagnosis of blunt cardiac injury can be made. Guidelines have been proposed that may facilitate the workup of this condition.⁶³

As an initial test, a 12-lead ECG should be obtained whenever blunt cardiac injury is suspected. If the ECG is normal, no further workup is required. If there is an ECG abnormality that does not necessitate treatment (e.g., non-specific ST-T wave changes), the patient should undergo monitored observation for 12 hours and then be discharged if there are no dysrhythmias and the ECG is normal at that time. If there is a more serious ECG abnormality (e.g., dysrhythmia, ST-segment elevation, or heart block), the patient should undergo observation for at least 24 to 48 hours and may require further testing and treatment, depending on the sequelae of the abnormality. In patients with hemodynamic instability and suspected blunt cardiac injury, echocardiography should be performed promptly. There is no role for cardiac enzyme analysis or cardiac troponin assay in this setting. The latter test may detect myocardial injury, but this information does not complement ECG and echocardiographic findings and has no clinical utility. Similarly, there is no role for nuclear medicine studies.

Management

Pump failure associated with cardiac contusion is usually the result of right heart failure, in that most hemodynamically significant cardiac contusions are caused by injury to the

anterior right ventricular free wall. Treatment of right heart failure from cardiac contusion consists of inotropic support and reduction of right ventricular afterload. Dysrhythmias secondary to cardiac contusion are treated in the same manner as dysrhythmias of any other etiology.

The commonly repeated adage that cardiac contusion should be treated similarly to MI is incorrect. Therapy for MI is based on the premises that the patient is likely to have concomitant coronary artery disease and that increased myocardial oxygen demand may result in extension of the evolving infarct or the creation of an additional infarct. However, most young trauma patients have normal coronary arteries, and increased myocardial oxygen demand is unlikely to extend cardiac contusion unless the heart sustains an additional blow. Generally, the goal in resuscitation of injured patients is to increase systemic oxygen delivery, which may increase cardiac work. In addition, unlike patients with MI, patients with myocardial contusion appear not to be at increased risk for cardiac complications from general anesthesia and surgery.

In the rare patient with cardiorrhexia who presents to the hospital with signs of life, the most common injury is right atrial perforation. Other lesions seen in patients with vital signs, in order of decreasing incidence, are left atrial perforation, right ventricular perforation, atrial septal perforation, ventricular septal perforation, coronary artery thrombosis, and valvular insufficiency (most commonly involving the tricuspid and mitral valves).^{58–60} Patients with cardiac rupture generally present with signs of pericardial tamponade and require rapid decompression. Placement of an intra-aortic balloon pump is often an effective temporizing measure while preparations are made for definitive repair.

Patients with blunt cardiac trauma who lose vital signs in the field or who go into cardiac arrest before arrival at the hospital generally should not be subjected to ED thoracotomy, because virtually none of these patients can be saved. Patients admitted with vital signs after suffering blunt cardiac rupture, however, have about a 50% chance of survival, and much of the mortality in these patients is attributable to associated injuries.

Blunt Aortic Injuries

Traumatic rupture of the aorta may account for as many as 10 to 15% of all traffic fatalities, and the majority of such injuries are fatal at the scene. Of those who survive the initial injury, 50% die in the first 24 hours and 90% die within the first month if the aorta is not repaired. Traumatic disruption of the thoracic aorta results from rapid deceleration and is produced by a shearing effect caused by differences in the mobility of the aorta above and below a point where the vessel is fixed. Most thoracic aortic disruptions in survivors occur at the aortic isthmus just distal to the origin of the left subclavian artery, where the aorta is fixed to a significant degree by the ligamentum arteriosum. Autopsy series reveal that as many as 40% of aortic injuries in nonsurvivors are not located at the isthmus, and the injuries tend to be complex.⁶⁴

Suspicion of an aortic injury is most often triggered by abnormal findings on a chest x-ray in a patient with a high-speed mechanism of injury and multiple other injuries. Most patients show no signs or symptoms on physical examination,

but some complain of interscapular pain or hoarseness, and some exhibit a difference in blood pressure or pulse fullness between the upper and lower extremities or between the right and left upper extremities. Accordingly, the diagnosis is usually made radiographically, often beginning with the recognition of mediastinal hemorrhage on a screening chest x-ray.

Numerous radiographic signs of a torn thoracic aorta have been described, all of which are manifestations of hemorrhage within the mediastinum that alters or obliterates the shadows seen on a normal chest radiograph. Mediastinal widening is the most frequent indicator of mediastinal hematoma from a torn thoracic aorta. Other important signs are obscuration of the detail of the contour of the aortic knob, opacification of the aortopulmonary window, depression of the left mainstem bronchus, apical cap, deviation of the nasogastric tube, and displacement of the esophagus to the right. These signs may be present in any combination or may be entirely absent.

Currently, high-speed CT with IV contrast is being liberally used for diagnosis of thoracic vascular injuries. Appropriately, this modality is employed in virtually all patients with abnormal chest x-rays and in many patients with normal x-rays whose injury mechanisms include a high degree of energy transfer. CT findings that are diagnostic of aortic injury include mediastinal hematoma, periaortic hematoma, intraluminal irregularity (intimal flap), acute coarctation, and abnormal aortic contour [see Figure 9]. Depending on the experience of the interpreting clinician, aortography may be eliminated in most of these patients before surgical repair; the sensitivity and specificity of CT in this setting approach 100%.^{21,65,66} Aortography should continue to be used for equivocal cases or cases in which spiral CT is not available.

MANAGEMENT

Essentially all aortic injuries associated with mediastinal hematomas should be repaired. The timing of repair, however, is less urgent than the timing of certain associated maneuvers that must be done, such as attainment of an adequate airway, control of external or cavitory hemorrhage, and evacuation of intracranial mass lesions. In general, if there is active bleeding from a blunt aortic injury, it will be massive; lesser amounts of bleeding from a chest tube often derive

from associated injuries. If intra-abdominal bleeding is present, laparotomy is indicated before repair of the torn thoracic aorta and before aortography. Similarly, in patients with intracranial hemorrhage that necessitates operative evacuation, craniotomy should take precedence over repair of the torn thoracic aorta.

While one is temporizing, stringent efforts must be made to prevent hypertension and reduce shear forces across the injury, ideally by means of IV beta blockade. Esmolol, because of its short half-life, is the best agent to use in these patients, who are at risk for sudden hypovolemic episodes of hypotension. The goals of medical therapy are a heart rate lower than 100 beats/min and a systolic blood pressure of approximately 100 mm Hg (in young and middle-aged patients) or 110 to 120 mm Hg (in elderly patients).²¹ Nitroprusside may have to be given to achieve these goals, but it should not be used until after adequate beta blockade is achieved, because it can increase intravascular shear forces when used alone. During pharmacologic treatment of aortic injuries, pulmonary arterial catheter monitoring is essential to prevent deleterious reductions in cardiac output and mixed venous oxygen saturation. With careful delayed operative management of aortic injuries, the risk of rupture is low but is not completely eliminated.^{21,67}

Traditional repair techniques include exposure of the aorta and arch through a left thoracotomy and direct repair or interposition graft placement. Although excellent results have been obtained with so-called clamp-and-sew techniques, most guidelines recommend use of some form of distal aortic perfusion (e.g., left atrial–distal aortic bypass or partial cardiopulmonary bypass with femoral cannulation). Systemic heparinization is required for cardiopulmonary bypass and has been shown to be safe with respect to hemorrhagic complications.^{68,69} The aortic arch is clamped between the common carotid and left subclavian arteries after these vessels and the distal aorta have been controlled. An interposition graft is required for most of these injuries, although 15 to 20% can be treated with suture repair alone. With distal aortic perfusion, the risk of paraplegia is approximately 5% and is independent of clamp time; without distal aortic perfusion, ischemic times longer than 30 minutes are associated with an exponential rise in the incidence of spinal cord injury.

Another potential advantage to using cardiopulmonary bypass is the ability to institute deep hypothermic circulatory arrest if needed. This technique involves cooling to a core temperature lower than 20°C (68°F) to induce cardiac standstill, turning off the pump, and operating on the unclamped aorta in a relatively dry field. Circulatory arrest can be safely maintained in this setting for approximately 30 to 45 minutes. This technique may be useful for patients who have previously undergone thoracic aortic surgery or who have complex tears involving the arch.

An evolving modality for the treatment of aortic injury is endovascular stent grafting. The rationale for the insertion of a stent graft in this population is that the aorta above and below the injury is usually normal, which is not the case in the atherosclerotic population. Toward this end, several reported series have described the use of this technique in both early and delayed settings.^{70–72} The results of these studies are very promising, demonstrating equivalent results when

Figure 9 Shown is an injury to the descending thoracic aorta (white arrow). A nasogastric tube can be seen in the esophagus, which is deviated to the right (black arrow).

compared with surgical repair, and are superior to those obtained with endovascular repair of aortic aneurysms and dissections.⁷³ However, caution must be used when interpreting these results as these are single-institution, primarily retrospective studies rather than randomized controlled trials, and long-term outcomes, including the incidence of late stent migration, erosion, thrombosis, and infection, are unknown. Furthermore, there are limitations with the current level of stent graft technology; however, this field is advancing rapidly to overcome these deficiencies, and reports on newer devices are encouraging.⁷⁴ Although endovascular stenting may eventually prove to be a durable and excellent long-term therapy in the treatment of traumatic aortic disruption, currently, its application should be reserved for those patients enrolled in a prospective trial, or who are a poor operative risk, or who refuse conventional surgery.

Great Vessel Injuries

Except for tears in the descending aorta, injuries to the thoracic great vessels, by any mechanism, are rarely seen in clinical practice; the best descriptions come from wartime and autopsy series. Indeed, postmortem studies reveal that patients with nonisthmus aortic and great vessel injuries rarely reach the hospital alive.⁷⁵ As many as 14% of patients have multiple great vessel injuries. Diagnosis and management of these injuries cover a wide spectrum of possibilities, depending on the mechanism of injury, presenting features, and associated injuries.

PENETRATING

Penetrating thoracic great vessel injuries are usually obvious. The presence of an entrance wound at the base of the neck or in the chest should alert the clinician to this possibility. If the patient is in shock, urgent operation is required. If the patient's condition stabilizes with resuscitation, an arteriogram should be performed to localize the injury.

Management

Exposure is most often obtained via a median sternotomy, with or without neck extension as needed for innominate, right subclavian, or carotid arterial injuries [see Table 1]. Exposure of the left subclavian artery can be more difficult, even through a sternotomy with a trap-door extension. For isolated injuries to the proximal subclavian artery, a fourth-interspace left posterolateral thoracotomy is most useful. For injuries to the middle and distal thirds, supraclavicular incisions or deltopectoral incisions—or, occasionally, a combination thereof—are appropriate, provided that inflow control can be achieved. When inflow control may not be achievable, as in cases involving injury at the thoracic outlet or the presence of a large hematoma, endovascular control of the proximal subclavian artery by means of a balloon catheter placed percutaneously through the femoral artery may be necessary. Moreover, a growing body of literature supports endovascular management of great vessel injuries.^{76–80} Endovascular repair may be considered in stable patients with arteriovenous fistula or pseudoaneurysm. As with endovascular repair of blunt aortic injuries, concerns with this modality primarily center on the lack of long-term outcomes in a typically young patient population.

Most penetrating wounds of the middle and distal segments of the great vessels are amenable to lateral repair or end-to-end anastomosis; injuries involving greater tissue destruction, for which grafts might be indicated, usually prove fatal before the patient arrives at the hospital. The subclavian artery is a notable exception to this general rule because the lack of elastic fibers in its tunica media makes it extremely friable. End-to-end anastomosis of an injured subclavian artery under any tension is doomed to failure. Accordingly, many subclavian injuries should be repaired with an interposition graft. Proximal injuries to the great vessels are best repaired by exclusion and bypass grafting with prosthetic material from the ascending aorta. Because bleeding is usually active, there is rarely enough time to arrange for cardiopulmonary bypass. In any case, cardiopulmonary bypass generally is not needed, except for rare cases of associated ascending or aortic arch injury.

BLUNT

Blunt injuries of the great vessels are typically the result of high speed and rapid deceleration. In postmortem examinations, pedestrians struck by motor vehicles have the highest rate of great vessel injuries. Patients with such injuries are rarely seen in the ED with signs of life.⁷⁶ Superior mediastinal hematoma is the most common finding during workup; its presence is an indication for further imaging with spiral CT or angiography. Besides vessel laceration with hematoma, presentations of blunt thoracic great vessel injury include dissection and thrombosis, which may be asymptomatic if localized to the proximal segments. Central neurologic injury may also be present, especially with carotid dissection. Associated stretch injury of the brachial plexus or the cervical nerve roots is common with subclavian artery injuries.

Management

Once the diagnosis is made, all great vessel injuries require intervention, typically surgical therapy; however, as mentioned above, an increasing number of reports describe successful endovascular treatment of these injuries in select patients. The exceptions to this are small intimal defects that are found incidentally as these typically require observation with repeat imaging and antiplatelet therapy. Surgery is contraindicated if neurologic injury is present, the injury is deemed unsurvivable, or a common carotid dissection has extended into the distal internal carotid artery. As with blunt aortic injuries, the timing of surgery should be tailored to the treatment priorities mandated by the associated injuries. When time permits, proximal lesions are best managed with cardiopulmonary bypass and hypothermic circulatory arrest. Arranging for these techniques is mandatory with injuries involving the ascending aorta and the arch.

Mediastinal blood seen on a chest CT scan probably more often derives from mediastinal venous injuries than from arterial injuries. These isolated venous injuries need not be repaired unless they are associated with cardiac tamponade or massive hemorrhage into a pleural space, both of which are uncommon. An exception is injury to the intrapericardial venae cavae, which is usually associated with tamponade. These injuries are caused by tearing of the mobile heart against the relatively fixed veins, particularly the inferior vena cava. In most cases, they can be repaired primarily.

Associated venous injuries are commonly encountered during exploration for great vessel arterial injury. If possible, they should be treated with lateral repair or patch venorrhaphy with pericardium or saphenous vein. However, ligation of these veins sometimes proves necessary and is generally well tolerated.

Conclusion

Thoracic trauma is a contributing factor in a majority of trauma-related deaths. With thorough physical examination and appropriate radiographic evaluation, the majority of these

injuries can be identified early and appropriate therapy can be initiated. Most thoracic injuries do not require operative intervention; rather, they may be treated with simple, lifesaving bedside procedures. However, when considering surgical intervention, many variables must be considered in this decision process, and each injury has unique issues to be addressed. Once the need for intervention is apparent, the critical decision for an appropriate surgical approach is based on a complete understanding of the location and nature of the injury.

6 OPERATIVE EXPOSURE OF ABDOMINAL INJURIES AND CLOSURE OF THE ABDOMEN

Erwin R. Thal, M.D., F.A.C.S., and Terence O’Keeffe, M.B., Ch.B., F.R.C.S.Ed.

Over the past two decades, the advent of nonoperative management techniques for many solid-organ injuries has led to a significant shift in the care of patients who have sustained abdominal trauma. The ever-improving accuracy of diagnostic modalities (computed tomography in particular) has also contributed to this shift.¹⁻⁴ Today, fewer patients require operative intervention for treatment of abdominal injuries. Those who do require such intervention make up a select group who continue to pose a significant challenge to surgeons. In our view, these patients are best managed by following a standardized operative approach, the aim of which is to diagnose, prioritize, and treat the injuries in an expeditious fashion so that the patient is not kept in the operating room any longer than necessary [see Figure 1]. Such an approach optimizes patient care by minimizing the risk of missed injuries and ensuring a rapid and efficient response by the members of the surgical team. Naturally, every patient’s care should be individualized as necessary. In general, however, a standardized operative approach, complemented by a solid knowledge of a variety of exposures and techniques, should allow the surgeon to deal with virtually any abdominal injury. In this chapter, we outline our recommended approach to operative intervention in patients with abdominal trauma.

Patient Preparation

The key to success in this setting is advance preparation aimed at covering all eventualities. Such preparation involves both the environment and the patient. The room should be warmed to ensure that the patient does not lose too much heat and become hypothermic. The instruments should be open on the back table, and specific instruments should be available when specific injuries are anticipated (e.g., a vascular set should be available when a vascular injury is suspected). A sufficient number of laparotomy pads should be on hand, and a retracting device with which the surgical team is familiar should be employed. Cell saver systems and rapid infusion systems can be useful adjuncts; if desired and available, they should be requested in advance.⁵

Patient preparation begins with the insertion of a nasogastric or orogastric tube and a Foley catheter. Invasive monitoring lines may have to be placed, and resuscitation should continue as the patient is being prepared. A broad-spectrum antibiotic should be administered intravenously before the initial incision is made. When the patient is correctly positioned on the operating table, skin preparation should extend from the sternal notch superiorly to include the anterior thorax. Thus, no further preparation will be required if a thoracic injury is identified or vascular control in the thorax is necessary. Thoracostomy, if required, can also be performed without the drapes being changed. Inferiorly, skin preparation should extend to the upper anterior thighs so that the proximal saphenous veins are available if a vascular reconstruction is required and so that distal vascular control can be achieved without undue delay.

All areas of the body that are not included in the skin preparation should be covered so as to prevent excessive heat loss, and warming devices should be placed if available. Sterile draping should be placed so as to allow access to all potential injuries. If the patient is in extremis and in danger of expiring, however, patient preparation should be limited to a rapid skin cleansing and surgery should commence immediately.

Incision and Initial Exploration

CHOICE OF INCISION

A midline celiotomy is the incision of choice. Its advantages are that it allows rapid and easy access to the abdominal cavity, with good exposure of the majority of the intra-abdominal organs and structures, and that it can be extended into a median sternotomy if necessary. Its main disadvantage is that it may not provide adequate exposure of injuries in the deep recesses of the upper quadrants.

Patients with previous midline incisions pose a challenge to the surgeon. If at all possible, an attempt should be made to enter the abdomen above or below the previous incision, in an area less likely to have adhesions. If this is not possible, an alternative incision, such as a chevron (bilateral subcostal) incision, should be considered. A chevron incision provides entry into the abdomen while avoiding any viscera that are adherent to the undersurface of the previous laparotomy scar. However, this incision takes more time, does not provide ideal exposure, and is associated with a higher morbidity; accordingly, it should be considered only when the circumstances are dire. Paramedian, subcostal, retroperitoneal, and flank incisions are not recommended, for much the same reasons.

INITIAL EXPLORATION

Once the peritoneal cavity has been entered, initial exploration proceeds in an orderly fashion so as to minimize hemorrhage and contamination, prevent iatrogenic injury, and facilitate the expeditious identification of injuries. The intestines are eviscerated, and gross blood is rapidly evacuated. Laparotomy pads are then rapidly placed in all four quadrants to pack the abdomen; the right upper quadrant is packed first, then the left upper quadrant, and finally the lower two quadrants. Care should be taken not to tear the falciform ligament or the fibrous capsule of the liver during this maneuver. Blood pressure may drop when the abdomen is decompressed. Anesthesia should be given the opportunity to catch up with resuscitation efforts at this point.

Once hemodynamic stability has been achieved, the intraperitoneal portion of the exploration is begun. In cases of blunt trauma, the temporary packs (except for those around the solid viscera) may now be carefully removed and any remaining blood evacuated. In cases of penetrating trauma, it is often easier initially to address the site of ongoing hemorrhage via a direct approach. Vascular injuries are controlled manually until proximal and distal

Figure 1 Algorithm outlines the approach to initial operative exposure in abdominal trauma patients.

control can be achieved. Mesenteric bleeding sites are clamped. Solid organs are initially packed as for blunt trauma, then treated with directed repair. In either scenario, bleeding that remains uncontrolled by packing requires immediate attention.

The enteric viscera are then examined in an orderly fashion. The anterior aspect of the stomach is inspected from the esophagogastric junction down to the pylorus. If an injury is present or is strongly suspected on the basis of the mechanism of injury or the presence of a hematoma or soilage, the posterior aspect of the stomach is examined by opening the gastrocolic omentum; this measure also permits examination of the anterior surface of the body of the pancreas. The exploration then continues distally along the course of the GI tract. If duodenal or pancreatic injury is a possibility, the duodenum is mobilized fully by means of a Kocher maneuver. The duodenojejunal junction at the ligament of Treitz is then inspected, and the small intestine is inspected all the way to the ileocecal valve. Both sides of the small intestine must

be examined, and particular care must be taken not to miss an injury at the mesenteric border. Careful consideration should also be given to the possibility of mesenteric vascular injuries, which may be manifested as mesenteric hematomas.

Next, the colon is inspected from the cecum to the rectum. If injuries are present or missile tracts are noted in proximity to a portion of the ascending or descending colon, the retroperitoneal portion of the colon is inspected by incising the white line of Toldt (the retroperitoneal reflection) so as to allow access to the posterior surface of the colon. Finally, the laparotomy pads around the solid organs are removed, one organ at a time, to permit inspection for hemorrhage or injury.

Once the peritoneal survey is complete, the retroperitoneum is inspected for potential injuries. Retroperitoneal hematomas are classified on an anatomic basis: zone 1 is the central area, bounded laterally by the kidneys and extending from the diaphragmatic hiatus to the bifurcation of the vena cava and the aorta; zone 2

comprises the lateral area of the retroperitoneum, from the kidneys laterally to the paracolic gutters; and zone 3 is the pelvic portion [see Figure 2]. Whether exploration is warranted for a retroperitoneal hematoma depends on the mechanism of injury and the location of the hematoma [see Priorities in Management, Repair of Retroperitoneal Injuries, *below*, and 7:10 *Injuries to the Great Vessels of the Abdomen*]. A careful evaluation is performed to identify possible occult injuries to organs (e.g., the pancreas, the duodenum, the retroperitoneal colon, the kidneys, and vascular structures).

The initial exploration concludes with a brief pelvic survey aimed at excluding injuries to the rectum or the distal urogenital tract (including the bladder). At the end of the operation, this initial inspection should be repeated, following the same sequence, to confirm that no injuries have been missed.

Operative Exposure

To expose the various organs that may be injured in patients who have sustained abdominal trauma, the surgeon must be familiar with a number of different techniques. In what follows, we detail the operative exposures that enable the surgeon to perform

the necessary repairs. The repairs themselves are described in greater detail elsewhere [see 7:7 *Injuries to the Liver, Biliary Tract, Spleen, and Diaphragm*; 7:8 *Injuries to the Stomach, Small Bowel, Colon, and Rectum*; 7:9 *Injuries to the Pancreas and Duodenum*; 7:10 *Injuries to the Great Vessels of the Abdomen*; and 7:11 *Injuries to the Urogenital Tract*].

AORTA AND BRANCHES

Control of the aorta can be gained at several different levels, depending on the site of injury. The supraceliac aorta can be exposed by incising the gastrohepatic ligament, retracting the left hemiliver laterally and cephalad, and retracting the stomach caudally. The esophagus and periesophageal fat pad are then mobilized laterally to permit identification of the abdominal aorta at the diaphragmatic hiatus, at which point the aorta can be encircled, clamped, or compressed. This exposure allows control of the aorta, but it is inadequate in terms of providing vascular access for definitive repair. Better exposure of the supraceliac aorta and its branches can be obtained by means of a left medial visceral rotation [see Figure 3]. To perform this maneuver, the splenorenal ligament is mobilized with a combination of sharp and blunt dissection. The left peritoneal reflection is incised from the splenicocolic flexure down the paracolic gutter to the level of the distal sigmoid colon. The left-side viscera are then gently mobilized to the midline (mostly with blunt dissection) in a plane anterior to Gerota's fascia. This technique allows exploration of the entire length of the abdominal aorta, the origin of the celiac axis, the origin of the superior mesenteric artery, the left iliac system, and the origin of the right common iliac artery. In addition, it facilitates control of the left renal vascular pedicle before exploration of a left-side zone 2 retroperitoneal hematoma. Alternatively, a variation on the standard left medial visceral rotation (the Mattox maneuver⁶) may be employed, in which the left kidney is also included in the organs that are rotated (the plane being anterior only to the muscles of the posterior abdominal wall). This variant may afford better access to the origin of the left renal artery.

If the injury is more distal, the aorta may be approached in a transperitoneal fashion. The small intestine is retracted to the right, the transverse colon is retracted cephalad, and the descending colon is retracted laterally. The peritoneum is then incised directly over the aorta, and the third and fourth portions of the duodenum are mobilized cephalad. The proximal limit of this dissection extends to the left renal vein, which may be divided if necessary to provide more cephalad access to the aorta. If ligation of the left renal vein is called for, it should be done at a point where the gonadal vein will be left intact to drain the kidney. A more limited dissection may suffice to expose the distal infrarenal aorta. Depending on the injury, distal control may or may not be required. Control may be achieved at the level of the distal infrarenal aorta, above the bifurcation.

Once again, if the patient is in extremis, formal dissection may be curtailed and proximal control achieved either by manually compressing the aorta against the spine at the level of the esophagogastric junction or by using an aortic occluder [see 7:10 *Injuries to the Great Vessels of the Abdomen*].

VENA CAVA AND BRANCHES

Access to the suprahepatic inferior vena cava can be gained only by either incising the central tendon of the diaphragm or by performing a median sternotomy and opening the pericardium. The infrahepatic inferior vena cava is exposed by performing a right medial visceral rotation (the Cattell-Braasch maneuver) [see Figure

Figure 2 Shown are the anatomic zones of the retroperitoneum: zone 1 (central), zone 2 (flank), and zone 3 (pelvic).

Figure 3 Left medial visceral rotation is performed to provide exposure of the entire length of the abdominal aorta, the left renal vasculature, the origins of the mesenteric arteries, and the common iliac bifurcation.

4]. The right colon is mobilized by taking down the hepatic flexure and then incising the right peritoneal reflection along the paracolic gutter. The colon is once again reflected medially toward the aorta in a plane anterior to Gerota's fascia with careful blunt dissection. If additional exposure is necessary, the inferior margin of the peritoneal incision may be extended to the root of the mesentery—and even beyond, if the inferior mesenteric vein is sacrificed. This exposure permits visualization of both the aorta below the origin of the superior mesenteric artery and the vena cava below the third portion of the duodenum. Exposure of the portion of the vena cava directly below the liver alone can be achieved by performing a Kocher maneuver [see Figure 5] with medial mobilization of the duodenum and the head of the pancreas.

LIVER

Mobilization of the liver begins with division of the round ligament (ligamentum teres), followed by takedown of the falciform ligament (to prevent iatrogenic trauma to the liver capsule during exposure and identification of other intraperitoneal injuries). This mobilization may be extended as far cephalad as is necessary. Further mobilization can be achieved by incising the left triangular ligament, with care taken not to injure the suprahepatic inferior vena cava at the diaphragmatic hiatus during the dissection. When visualization of the right hemiliver is required, the falciform ligament should be incised to its most superior extent, and the right triangular ligament should then be carefully divided. This

step is challenging and may have to be performed partly by palpation, with care taken not to injure the inferior vena cava, the hepatic veins, or the phrenic vessels [see 7:7 *Injuries to the Liver, Biliary Tract, Spleen, and Diaphragm*].

SPLEEN

The spleen can be mobilized into the midline by dividing the phrenicosplenic and splenorenal ligaments with a mixture of sharp and blunt dissection. In cases where the spleen has been injured by blunt trauma, these ligaments often are already disrupted, and this disruption facilitates the dissection. The splenocolic ligament often contains sizeable blood vessels that must be controlled, and the gastrosplenic ligament contains the short gastric arteries. Once the spleen is mobilized into the midline, control of the vascular pedicle can be achieved, the splenic injury can be assessed, and splenorrhaphy or splenectomy can be performed as appropriate [see 7:7 *Injuries to the Liver, Biliary Tract, Spleen, and Diaphragm* and 5:25 *Splenectomy*].

PANCREAS

Intraoperative evidence of a central hematoma, peripancreatic edema, or bile staining in the retroperitoneum or the lesser sac raises the possibility of pancreatic injury. The contents of the lesser sac can be visualized by performing a direct inspection through the gastrohepatic ligament or by dividing the ligament. Alternatively, access can be gained by dividing and ligating two or three gas-

troepiploic arcades of the gastrocolic ligament. If it proves necessary to explore the pancreas, the stomach is separated from the transverse colon by completing the division of the gastrocolic ligament, and a Kocher maneuver is performed to reflect all portions of the duodenum medially, along with the head of the pancreas. The peritoneum lateral to the duodenum is incised, and careful blunt dissection is employed to mobilize the duodenal loop from the common bile duct superiorly to the superior mesenteric vein inferiorly. This mobilization allows inspection of the anterior and posterior surfaces of the head of the pancreas, as well as the uncinate process. If injury to the body or tail of the pancreas is suspected, the splenorenal and splenocolic ligaments are incised. At this point, the spleen and then the pancreas can be mobilized medially to a position near the level of the superior mesenteric vessels, and the anterior and posterior aspects of the body and tail of the pancreas can be examined [see 7:9 *Injuries to the Pancreas and Duodenum*].

KIDNEYS

Operative exposure of the kidneys starts with either a left or a right medial visceral rotation, depending on which kidney is involved. The renal vascular pedicle should be controlled before any hematoma in Gerota's fascia is opened [see 7:11 *Injuries to the Urogenital Tract*]. Repair of the kidney may be facilitated by mobilizing the organ out of Gerota's fascia and retracting it medially.

DUODENUM, BILIARY TRACT, AND SMALL INTESTINE

Exposure of the posterior surface of the duodenum is achieved by means of a Kocher maneuver [see *Pancreas, above, and Figure 5*]. This technique is also used when injury to the distal extrahepatic biliary system is suspected. The proximal extrahepatic biliary tree is visualized by using a Kocher maneuver in conjunction with local exploration of the porta hepatis. In patients with injuries to the distal duodenum or the proximal jejunum, division of the ligament of Treitz may also be necessary for accurate identification of the site of injury. Because of the mobility of the small intestine, injuries to this structure generally are readily identified and repaired without additional mobilization.

COLON AND RECTUM

Evidence of staining, pneumatosis, or hematoma in proximity to a portion of the ascending or descending colon, particularly in the setting of related injuries or missile tracts, should prompt a full evaluation of the colon. Because the colon is a partially retroperitoneal structure, the retroperitoneal reflection must be incised to allow inspection of the posterior surface of the colon. Sometimes, rectal injuries are not accessible via an intraperitoneal approach; in this situation, consideration should be given to a diverting colostomy and presacral drainage [see 7:8 *Injuries to the Stomach, Small Bowel, Colon, and Rectum*].^{7,8}

Figure 4 Right medial visceral rotation is performed to provide exposure of the inferior vena cava, the infrarenal abdominal aorta and iliac vessels, and the right renovascular pedicle.

Figure 5 The Kocher maneuver reflects the duodenum and the pancreatic head from the retroperitoneum, allowing access to the infrahepatic inferior vena cava as well as to the distal common bile duct, the duodenum, and the pancreatic head.

Priorities in Management

CONTROL OF HEMORRHAGE

In the event that the patient remains hemodynamically unstable because of persistent uncontrolled hemorrhage, the primary focus of the initial exploration is control of bleeding. As noted (see above), the approach to hemorrhage control differs depending on whether the patient sustained blunt trauma or penetrating trauma. In cases of blunt trauma with bleeding from a solid organ, the first thing that should be done is to attempt repeat packing of the specific bleeding site with a sufficient number of laparotomy pads. This is an important skill to master and can be effective as a temporizing measure until either more definitive vascular control can be achieved or coagulopathy can be corrected. In cases of penetrating trauma, bleeding is more effectively managed by means of either vascular control just proximal and distal to the site of injury or direct control at the bleeding site.

When significant hemorrhage is anticipated, control of the injured vessel should be obtained by the operative techniques discussed previously [see *Operative Exposure, above*]. Given the possibility of exsanguinating hemorrhage, the surgeon must be prepared to gain proximal aortic control at the diaphragmatic hiatus or even within the chest via a left lateral thoracotomy. For immediate control, the aorta can be manually compressed at the hiatus; a padded Richardson retractor, an aortic compressor, or an assistant's hand can then take over this function to allow the surgeon to continue the exploration. If a need for prolonged proximal aortic control is anticipated, an atraumatic aortic vascular clamp should

be placed. Injuries to the proximal abdominal aorta often necessitate that the vessel be controlled in the chest to permit repair.

In patients who have sustained parenchymal injuries to solid viscera, control of the vascular inflow is crucial as both a diagnostic and a therapeutic maneuver. Gaining control of the splenic hilum effectively arrests further splenic hemorrhage. Similarly, use of the Pringle maneuver [see 7:7 *Injuries to the Liver, Biliary Tract, Spleen, and Diaphragm*] to control the vessels in the porta hepatis (the hepatic artery and the portal vein) helps determine the source of perihepatic hemorrhage. This maneuver is initially performed by digitally compressing the portal structures; if digital compression causes the hemorrhage to diminish, the surgeon's hand is replaced with an atraumatic vascular clamp or a Rumel tourniquet. Although the Pringle maneuver can be maintained for at least 30 to 45 minutes without causing permanent liver damage, the clamp or tourniquet should be removed as soon as is feasible. In the vast majority of cases of liver trauma—aside from those involving an injury to the retrohepatic vena cava—the use of the Pringle maneuver, combined with perihepatic packing, should arrest hemorrhage.

In patients who have sustained injuries to the retrohepatic vena cava, it may be necessary to gain vascular control by performing hepatic exclusion before definitive repair can be attempted [see 7:7 *Injuries to the Liver, Biliary Tract, Spleen, and Diaphragm*]. Hepatic exclusion may be achieved by means of either atriocaval shunting (which is rarely if ever used^{9,10}) or occlusion of the inferior vena cava both above and below the liver. The latter may lead to significant hemodynamic instability, particularly in volume-depleted

patients; however, it may reasonably be considered in patients whose volume status is adequate. Complete hepatic exclusion involves both (1) atriocaval shunting or clamping of both the infrahepatic and the suprahepatic inferior vena cava and (2) control of hepatic arterial and portal venous inflow.¹¹ In general, injuries to the retrohepatic vena cava are best dealt with by means of damage-control procedures.

Hepatic parenchymal hemorrhage can be challenging, and any of a number of techniques may be used to control it, depending on the location, type, and degree of bleeding. These techniques range from simple electrocauterization and parenchymal suturing to argon beam cauterization, direct vessel ligation, hepatotomy, and even resection [see 7:7 *Injuries to the Liver, Biliary Tract, Spleen, and Diaphragm*].^{12,13} In difficult cases, it may be advisable to perform an abbreviated laparotomy, pack the liver extensively, and transport the patient to the angiography suite, where selective embolization can be performed; the patient can then be transported to the ICU, undergo warming, and have any coagulopathy corrected before returning to the OR to have the packs removed.

Mesenteric bleeding can usually be controlled with manual compression of the vessel followed by suture ligation. Retroperitoneal hematomas are often harbingers of vascular injury, and proximal and distal vascular control should be obtained before exploration is initiated [see 7:10 *Injuries to the Great Vessels of the Abdomen*]. Typically, bleeding from injured hollow viscera is minor and can be controlled by repairing the injury; on occasion, however, temporary hemostatic suturing or stapling may be required.

CONTROL OF CONTAMINATION

Once hemorrhage has been controlled, the next priority is to control contamination. All gross spillage should be removed from the abdomen with suction and laparotomy pads, and further contamination should be prevented by temporarily closing small enterotomies with Babcock clamps (or, alternatively, with a continuous suture or skin staples). When multiple enterotomies are present, suture closure is preferred (to ensure that multiple clamps are not present in the operative field). If the injuries are in close proximity, the preferred method of controlling intestinal spillage is to apply atraumatic bowel clamps at both the proximal and the distal end of the injury site. Alternatively, if the injured segment will have to be resected, rapid control of further spillage can be obtained by firing a GI stapler at each end of the injured segment.

REPAIR OF VASCULAR INJURIES

Once intestinal contamination has been dealt with, the next priority is definitive vascular repair [see 7:10 *Injuries to the Great Vessels of the Abdomen*]. If proximal and distal control of the injured vessel has not already been obtained, it is obtained at this point. The extent of the vascular injury is determined, dead or devitalized tissue is carefully debrided, and vessel continuity is reestablished if possible. If the injury is not amenable to primary repair and the vessel cannot be ligated, autogenous tissue should be obtained (usually from the proximal greater saphenous vein) and used for either patch angioplasty or interposition grafting. If no suitable autogenous venous tissue is available, synthetic material may be considered as an alternative vascular conduit. For aortic or iliac arterial injuries, primary ligation with subsequent extra-anatomic bypass is an acceptable alternative. In cases in which an abbreviated laparotomy is necessary, vascular shunting may serve as a substitute for definitive repair until hypothermia, coagulopathy, and acidosis are corrected.

REPAIR OF DAMAGED OR DEVITALIZED BOWEL

Once vascular injuries have been addressed, the next priority is to repair any enteric injuries [see 7:8 *Injuries to the Stomach, Small Bowel, Colon, and Rectum*]. Because the stomach is a large and well-vascularized organ, gastric injuries are usually amenable to primary repair. Injuries to the small intestine that involve less than 50% of bowel circumference after debridement of devitalized edges can be repaired with either a single-layer or a two-layer closure; single-layer closure, being less likely to compromise the lumen of the bowel, is generally preferred. In cases involving multiple enterotomies in close proximity or a large area of devitalized tissue, a segmental enterectomy with primary anastomosis is preferable. The anastomosis may be either hand-sewn or stapled; the latter tends to be more expeditious but less cost-effective.

Solitary injuries to the colon that do not necessitate resection after debridement and are not associated with multiple transfusions or significant gross contamination are managed by means of primary closure. Large or multiple injuries to the right colon are best managed with a right hemicolectomy followed by an immediate ileocolic anastomosis. Similar injuries to the left colon are generally treated with resection and proximal diversion. The distal limb may be exteriorized as a mucous fistula, or, if inadequate bowel length renders diversion impossible, a Hartmann procedure may be performed.¹⁴⁻¹⁶

REPAIR OF RETROPERITONEAL INJURIES

Once all injuries within the peritoneal cavity have been addressed, the next priority is to inspect the retroperitoneum once more, paying particular attention to the possibility of hematoma expansion. The decision whether to explore a retroperitoneal hematoma is based on the mechanism of injury and on the zone in which the injury is located. All zone 1 hematomas should be explored regardless of the injury mechanism: they signal possible aortic, vena caval, duodenal, or pancreatic injury. Zone 2 and 3 hematomas should be explored in cases of penetrating trauma but not, as a rule, in cases of blunt trauma (with the exception of expanding zone 2 hematomas).

Before a retroperitoneal hematoma is opened, proximal vascular control should be obtained so that hemorrhage will be minimized once the effect of the tamponade has been lost. Injuries to retroperitoneal organs (e.g., the kidneys, the pancreas, and the adrenal glands) are treated by means of debridement or resection, with drainage as indicated. Vascular injuries are repaired as discussed previously [see *Repair of Vascular Injuries, above, and 7:10 Injuries to the Great Vessels of the Abdomen*].

Closure

GENERAL TECHNIQUE

Once the abdominal exploration has been completed, the abdomen is copiously irrigated with an isotonic crystalloid solution. The closure method employed is typically determined on the basis of five main considerations: (1) the degree of blood loss, (2) the volume of resuscitation fluid received, (3) the degree of contamination, (4) the patient's perceived nutritional status, and (5) the patient's hemodynamic stability. In cases that necessitate an abbreviated or damage-control procedure, the speed with which the closure can be performed may be the most important factor. Provided that the risk of subsequent abdominal compartment syndrome (ACS) is considered to be low, every effort should be made to close the fascia. Fascial closure is usually accomplished with a continu-

Figure 6 Retention sutures may be used to bolster fascial closure in wounds at high risk for breakdown. (a) Sutures are placed in the subfascial plane. (b) The defect is approximated, and the sutures are tied over skin bridges.

ous absorbable or nonabsorbable monofilament suture, though it may also be accomplished with interrupted sutures. The rate of fascial dehiscence is essentially the same for the two techniques; however, the extent of dehiscence is more limited when closure is done with interrupted sutures.^{17,18} With either technique, it is important not to place excessive tension on the fascial tissues.

In cases where there is a specific reason to be concerned about possible dehiscence (e.g., in patients who are malnourished or obese or are receiving steroid therapy), large monofilament sutures may be placed at intervals within the standard closure to serve as retention sutures. They may be tied over bolsters created from a red rubber catheter or over plastic skin bridges [see Figure 6]. If rapid closure is required, the abdomen may be closed with four or five retention sutures of this type that are placed through the abdominal wall and just above the peritoneum. These sutures must be checked daily and should be loosened if there is evidence that they are cutting through the abdominal skin as a consequence of edema creating increased tension on the wound.

SKIN CLOSURE

If the patient has minor injuries without evidence of enteric contamination, the skin may be closed primarily. Stapled closure is most expeditious, but suture closure is also acceptable. A degree of clinical judgment is required in assessing a wound's suitability for closure. If the skin is closed primarily, it should be inspected daily, and the wound should be opened without delay if there is concern about subsequent infection. Alternatively, primary delayed closure may be performed by leaving the wound open, packed with moist gauze. If the wound shows no evidence of infection when examined after 3 to 5 days, it may be closed with Steri-Strips or with interrupted sutures that are placed (without being tied) during the original operation. If intraperitoneal contamination has occurred, either primary delayed closure should be performed or the wound should be packed and left to heal by secondary intention.

ABBREVIATED OR DAMAGE-CONTROL LAPAROTOMY

If a patient remains unstable after surgical bleeding and contamination have been controlled or is cold and coagulopathic, an

abbreviated or damage-control procedure is indicated. It may be necessary to perform a rapid abdominal closure—with the proviso that further exploration, as well as definitive repair of injuries that have been temporarily controlled, will be required. The decision to perform a damage-control procedure should be made at an early stage, before the so-called lethal triad (hypothermia, acidosis and coagulopathy) has had time to develop. Damage control has undoubtedly led to improved survival for trauma patients, but it has also led to an increase in the number of patients whose abdomens are left open.¹⁹

TEMPORARY ABDOMINAL CLOSURE

When a damage-control procedure is required, it is often most expedient to perform a rapid temporary abdominal closure, then to transport the patient to the intensive care unit. This measure may also be necessary in patients whose abdomens cannot be closed because of intestinal and organ edema caused by intraoperative fluid resuscitation. The simplest form of temporary abdominal closure is the use of towel clips to close only the skin [see Figure 7], in conjunction with the application of a bioocclusive dressing to control fluid loss and contamination. This closure, however, leaves the patient still at risk for subsequent ACS.

The first temporary abdominal dressing described was the so-called Bogotá bag—that is, an empty intravenous fluid bag that was cut in half and sewn to the wound edges. This dressing can still be used in circumstances where no other equipment is available. The so-called vacuum pack technique involves the placement of a sterile plastic drape over the bowel contents and under the fascia, followed by insertion of two or more suction drains, over which sterile towels or open laparotomy pads may be placed. To minimize heat loss and insensible fluid loss, an adherent bioocclusive dressing is placed over the entire dressing and the abdominal wall, with the drains attached to suction. Several commercial devices are now available that can be used to facilitate temporary closure of the open abdomen; these include the VAC Abdominal Dressing System (Kinetic Concepts Inc., San Antonio, Texas) and the Wittmann Patch (Star Surgical, Burlington, Wisconsin).^{20,21}

MANAGEMENT OF THE OPEN ABDOMEN

Once the patient's physiologic status has stabilized, he or she should be returned to the OR for reexploration and definitive repair of any remaining injuries [see Figure 8], preferably within 48 hours after the first operation. At this juncture, the abdomen should be assessed for the feasibility of closure. In some patients, the fascial edges cannot be approximated, because of edema; in others, reapproximation may cause a significant rise in intra-abdominal pressure, as evidenced by a rise in pulmonary inspiratory pressures. These patients are at risk for ACS, and their abdomens should be left open.

At this point, if temporary abdominal coverage continues to be required, a temporary abdominal dressing should be placed that attempts to prevent fascial retraction and the associated increased risk of nonclosure of the abdomen. Options include dynamic retention sutures, the Suture Tension Adjustment Reel (STAR) (WoundTEK, Inc., Newport, Rhode Island), the Wittmann Patch, nonabsorbable mesh, fascial zippers, and the VAC Abdominal Dressing System.²⁰⁻²⁵ Once the dressing is placed, it should be

Figure 7 Shown is a “quick out” closure with surgical towel clips.

Figure 8 Algorithm outlines the approach to the open abdomen in a patient with abdominal injuries.

examined every 24 to 48 hours, depending on the degree of contamination; this is often best done in the OR, but it may also be done in the ICU if the patient remains unstable. At every subsequent procedure, the fascia should be assessed for the possibility of closure. Partial closure of the incision (i.e., closure of the cephalad and caudad portions) should be considered, even if full closure cannot be accomplished. In approximately 50% of patients, closure of the fascia is not possible; however, there is some evidence to suggest that this figure may be lowered by employing some of the devices now commercially available.^{20,26,27}

ABDOMINAL COMPARTMENT SYNDROME

Patients who undergo fascial closure are at risk for ACS as a consequence of ongoing resuscitation efforts and associated bowel and organ edema. ACS is defined as intra-abdominal hypertension greater than 25 mm Hg in conjunction with dysfunction of one or more organ systems (e.g., pulmonary, renal, or cardiac).^{28,29} Intra-abdominal pressure is determined indirectly by measuring bladder pressure. Bladder pressure can be measured by using an arterial transducer at the level of the symphysis pubis that is connected to the urinary catheter after 30 to 50 ml of sterile water has been introduced. Alternatively, an idea of the intra-abdominal pressure can be gained by raising the Foley tubing above the bed after instillation of the water, then measuring the column.³⁰ A rising trend in pressure can be as significant as a single elevated measurement. Patients who have undergone a long operation, have been the object of vigorous resuscitation efforts, or who have sustained mul-

Figure 9 Mesh may be used for temporary or permanent abdominal closure in patients at risk for increased abdominal pressure. (a) Mesh is sutured into the fascial plane, then covered with a split-thickness skin graft. (b) The abdominal defect is closed with mesh.

multiple injuries should be monitored closely for the development of ACS. If the diagnostic criteria for ACS are met, prompt abdominal decompression is indicated. On occasion, this measure may have to be carried out at the bedside in the ICU.

Occasionally, ACS develops in patients who have a temporary abdominal dressing in place (so-called tertiary ACS). Accordingly, it is mandatory to continue to monitor intra-abdominal pressure in these patients.²⁹

CLOSURE OF THE OPEN ABDOMEN

It is important to close the abdomen as early as possible: an open abdomen carries an increased risk of desiccation of the intestines and subsequent fistula formation. In certain patients, however, despite aggressive efforts to close the fascia, it proves impossible to accomplish primary closure, even after many days and repeated procedures. There are several techniques that may be employed to obtain final closure in this situation.

The simplest method is to allow granulation tissue to form over the omentum and the exposed intestines and later, when there is a good clean granulation bed with no evidence of infection, to place a split-thickness skin graft. Alternatively, a piece of absorbable mesh may be placed; this helps facilitate dressing changes, provides a modicum of protection to the intestines, and serves to control evisceration [see Figure 9]. A skin graft can then be placed in the same fashion, once a granulation bed has developed.

Another option is to employ relaxing incisions, either to allow a skin-only closure or to allow the skin to be closed over absorbable mesh. Open skin wounds should be left open to heal by secondary intention. Unfortunately, the use of relaxing incisions will not prevent the formation of large ventral hernias, which will have to be repaired at a later date.

Abdominal fascial defects may also be closed with sheets of nonincorporable synthetic material (e.g., Gore-Tex; W. L. Gore and Associates, Inc., Newark, Delaware). The advantages of these nonabsorbable materials are that they do not react with tissue and that they are associated with a low incidence of complications (e.g., fistula formation). The disadvantages are that they are expensive and that they must ultimately be removed unless the skin can be closed over them to prevent contamination.

Another option for achieving primary closure of the abdomen is component separation of the rectus sheath. The external oblique aponeurosis is incised and mobilized, along with the rectus sheath, to bring the fascia to the midline. Defects as wide as 14 to 20 cm can be bridged in this fashion, but recurrent hernia rates remain high.³¹

Several biosynthetic materials are now available to be used for bridging abdominal fascial defects. One such material is Surgisis (Cook Biotech Inc., West Lafayette, Indiana), a porcine submucosal matrix that can provide scaffolding for the ingrowth of fibrous tissue while supporting abdominal contents and permitting skin closure.³² Another is AlloDerm (LifeCell Corp., Branchburg, New Jersey), a denatured human cadaveric product that can be used in a similar fashion to replace denuded fascia or to bridge the fascial gap in cases where primary closure cannot be accomplished.^{33,34} At present, long-term follow-up data are lacking for both products, and their use is further limited by their very high cost.

Morbidity is very high in these patients; subsequent complications range from prolonged ventilator dependence to enteric fistulas to massive ventral hernias.^{35,36} Major ventral hernias represent a significant technical challenge and should not be repaired until the patient's recovery from injury is complete and his or her nutritional and general status has returned to normal. This may take as long as 12 months from the time of the initial trauma.

7 INJURIES TO THE LIVER, BILIARY TRACT, SPLEEN, AND DIAPHRAGM

*Clay Cothren Burlew, MD, FACS, and Ernest E. Moore, MD, FACS**

Injuries to the Liver

The liver is the most commonly injured solid organ in blunt trauma, comprising 5% of all trauma admissions, and because of its size is frequently involved in penetrating trauma. Following blunt trauma, the most commonly injured structures are the parenchyma and hepatic veins. Blunt forces dissipate along segments of the liver and along the fibrous coverings of the portal triad structures; the hepatic veins, however, are not so insulated. Given its size and location within the abdomen, the liver is also commonly involved in penetrating trauma. Stab wounds typically result in direct linear tears, whereas gunshot wounds or shotgun wounds result in significant cavitory injuries attributable to blast effect and the “tumbling” of the missile within the liver parenchyma. Thus, arterial injury is more common with penetrating trauma.

Over the past 20 years, nonoperative management (NOM) of liver injuries has evolved to become the prevailing therapeutic strategy for blunt hepatic trauma. Several concurrent changes resulted in this paradigm change. First was the realization that diagnostic peritoneal lavage (DPL) was sensitive but not specific for identifying intraperitoneal hemorrhage that necessitated operative management. Surgeons recognized that many laparotomies undertaken for a positive DPL were associated with liver injuries that did not require intervention for bleeding.¹ Second, trauma surgeons noted that nonbleeding hepatic venous injuries, if manipulated at laparotomy, often resulted in more hemorrhage and sometimes even death.² Furthermore, it became conspicuous that with hemostasis achieved in the operating room, recurrent postoperative bleeding was rare. Therefore, surgeons queried whether hepatic venous injuries, which are low-pressure system injuries, could heal without intervention. Finally, computed tomography (CT) provided a reliable method for diagnosing and grading liver injuries.

INITIAL EVALUATION

The first step in patient management in the emergency department (ED) is the primary survey and evaluating the patient's response to resuscitation. Patients with hemodynamic instability and either a penetrating abdominal wound or intra-abdominal hemorrhage noted on focused abdominal sonography for trauma (FAST) examination should undergo urgent laparotomy. Although the definitive diagnosis of a hepatic injury may not be made, laparotomy should be

undertaken [see Operative Exposure and Hemorrhage Control, *below*]. For hemodynamically stable patients, further evaluation is warranted. Abdominal examination includes inspection for abdominal wall abrasions or ecchymosis and assessing for distention, rigidity, tenderness, or rebound. Although DPL was used routinely to evaluate abdominal trauma in the ED a decade ago, it has been supplanted by FAST in most hospitals over the past decade. The advantage of FAST is that it is noninvasive, portable, rapid, and easily repeatable over the patient's ED course. Any of the three standard views of the abdomen—right and left upper quadrants and pelvis—can reveal intra-abdominal fluid, which is presumed to be hemorrhage unless the patient has liver disease with known ascites. Although ultrasonography is sensitive for detecting intraperitoneal fluid greater than 400 mL, it does not reliably determine the source of hemorrhage or extent of solid-organ injuries and does have limitations in some settings, such as subcutaneous emphysema, morbid obesity, and retroperitoneal hemorrhage from pelvic fractures.^{3,4}

Patients with evidence of intra-abdominal fluid should undergo CT unless laparotomy is indicated. Occasionally, the first ultrasound views of the abdomen may be normal; repeating the ultrasonography as a second snapshot in time is critical for patients at high risk for injury. FAST is not 100% sensitive⁵; therefore, diagnostic peritoneal aspiration (DPA) is warranted in hemodynamically unstable patients without a defined source of blood loss to rule out abdominal hemorrhage, and some prefer DPA as the initial screening tool in the presence of pelvic fractures as well. The diagnostic measures advocated for the severely injured or unstable patient (FAST, DPA) are those that can easily be performed in the trauma bay. Transport of a hypotensive patient out of the ED for CT scan evaluation is hazardous; monitoring is compromised, and the environment is suboptimal for dealing with acute problems. On the other hand, CT is very desirable in the hemodynamically stable patient at risk for liver injury because laparotomy may provoke further hepatic bleeding.

IMAGING AND INJURY GRADING

Since its initial use in the early 1980s, CT has become a routine part of trauma evaluation. With multislice helical scanning, the entire torso can be scanned in under 5 minutes. Patients with fluid on a FAST examination, considered a “positive FAST,” who do not have immediate indications for laparotomy and are hemodynamically stable undergo CT to quantify their injuries. Additionally, patients with persistent abdominal tenderness, significant abdominal wall trauma, distracting injuries, or altered mental status should undergo CT. Although the majority of abdominal penetrating injuries that violate the peritoneum require laparotomy, the exception

* The authors and editors gratefully acknowledge the contributions of the previous author, Jon M. Burch, MD, FACS, to the development and writing of this chapter.

is penetrating trauma isolated to the right upper quadrant. In hemodynamically stable patients with the trajectory of penetrating trauma confined to the liver by CT scan, nonoperative observation is an option.^{6,7}

The American Association for the Surgery of Trauma (AAST) developed a grading scale to provide a uniform definition of liver injuries [see Table 1 and Figure 1].³ Solid-organ injury grading permits effective transfer of information between treating physicians and predicts failure rates and complication rates of NOM. In addition to grading the liver injury, specific findings that should be noted on a CT scan in patients include contrast extravasation (i.e., a “blush”), the amount of intra-abdominal hemorrhage, and the presence of pseudoaneurysms [see Figure 2]. Additionally, associated enteric injuries mandating laparotomy should be excluded.

NONOPERATIVE MANAGEMENT

Indications for Nonoperative Management

Nonoperative management of blunt solid-organ injuries is appropriate in hemodynamically stable patients who do not have overt peritonitis or other indications for laparotomy. High-grade injuries, a large amount of hemoperitoneum, contrast extravasation, and pseudoaneurysms are not absolute contraindications for NOM; however, these patients are at high risk for failure and are more likely to need angioembolization.^{8–12} Likewise, there is no patient age cutoff for the NOM of solid-organ injuries. In fact, in contrast to splenic trauma, where age over 55 years is considered a relative indication for operative intervention, older patients appear to be more likely to survive NOM. A multidisciplinary approach including angiography with selective angioembolization has improved NOM success rates as well as survival.^{2,10,11} Patients with grade III or higher injuries should be admitted to the surgical intensive care unit (ICU) with frequent monitoring of their hemodynamics, abdominal examination, and hemoglobin level. Ultrasound surveillance for fluid collections (blood or bile) is warranted for grade IV and V injuries.

Over 80% of patients with liver injuries may be managed nonoperatively. Patients who require laparotomy typically fail NOM in the first 24 to 48 hours.^{2,8} One of the early studies to test the application of nonoperative therapy in 1995 supported its broad application with an overall success rate greater than 85% in hemodynamically stable patients, despite substantial hemoperitoneum documented by CT.⁸ Of the 8% of patients who failed NOM, half required operation as a result of associated injuries (i.e., enteric or pancreatic injuries), whereas half underwent laparotomy for hepatic-related hemorrhage. Perhaps not surprisingly, those patients who failed NOM had increasing rates of failure associated with increasing grades of hepatic injury, with grade V injuries having a greater than 20% failure rate. Subsequent studies have reported failure rates of 14% in grade IV injuries and 23% in grade V injuries.⁹ Similarly, the amount of hemoperitoneum appears to correlate with successful management; patients with a large amount of hemoperitoneum (i.e., blood extending into the pelvis) are more likely to fail NOM. However, predicting which patients will ultimately require laparotomy has yet to be accomplished.

An indication for angioembolization to address ongoing hepatic bleeding is transfusion of 4 units of red blood cells

(RBCs) in 6 hours or 6 units of RBCs in 24 hours. Recurrent hemodynamic instability, however, often requires laparotomy with perihepatic packing for hemostasis. Patients with contrast extravasation identified on CT scan, indicating arterial hemorrhage, should also be considered as a candidate for hepatic angiography. Originally, evidence of extravasation was an indication for laparotomy; however, the advent of endovascular techniques has resulted in effective hemostasis in selected cases. Angioembolization is particularly helpful in hemodynamically stable patients with contrast pooling within the hepatic parenchyma.¹⁰ Patients with contrast extravasation into the peritoneal cavity are more likely to require laparotomy,¹¹ but cases of successful embolization have been reported.¹²

Although not universally embraced, selected patients with penetrating injuries to the right upper quadrant may be candidates for NOM.^{6,7,13,14} Patients must have a CT scan that documents confinement of the injury to the liver [see Figure 3]. Additionally, the patient must be hemodynamically stable, have a reliable physical examination without evidence of peritonitis (i.e., cannot have depressed mental status), and not require blood products. Patients should be admitted for serial examination and hemoglobin monitoring; any alteration should prompt laparotomy. Violation of the diaphragm has the risk of a biliopleural fistula. An alternative approach is to perform laparoscopy to confirm trajectory of the missile or knife and to repair the diaphragm. In addition to avoiding the morbidity of a laparotomy, the success of NOM for penetrating trauma has resulted in decreased hospital stays, lower transfusion requirements, and diminished abdominal infection rates.

Follow-up Imaging

Based on the available literature, clear indications for repeat imaging in asymptomatic patients are lacking, although patients with grade IV or higher injuries are at substantial risk of complications.^{15,16} Repeat imaging in patients with complex hepatic injuries should be performed with bedside ultrasonography. Patients with evidence of right upper quadrant fluid collections or clinical deterioration (increasing abdominal pain, worsening liver function tests, unexplained fever) should undergo CT to exclude a biloma, an abscess, necrosis, or hemorrhage.^{15,16} In asymptomatic patients, the trend in several institutions has been to repeat CT scans in patients with all high-grade injuries, that is grade IV or higher. The rationale is to exclude a delayed pseudoaneurysm, which may rupture, and to document healing, which may be used to guide activity limitations. If postdischarge routine imaging is performed, it is typically done more than 4 weeks after injury.

OPERATIVE EXPOSURE AND HEMORRHAGE CONTROL

In penetrating abdominal injuries not suitable for NOM and in blunt abdominal injuries when NOM is contraindicated or has failed, exploratory laparotomy is performed.

Exposure

Visualization of the right hemiliver [see Figure 4] is hindered by the posterior attachments and by the right lower costal margin. Exposure of the right hemiliver is facilitated by

Table 1 AAST Organ Injury Scales for Liver, Biliary Tract, Diaphragm, and Spleen

Injured Structure	AAST Grade	Characteristics of Injury	AIS-90 Score
Liver*	I	Hematoma: subcapsular, nonexpanding, < 10% surface area	2
		Laceration: capsular tear, nonbleeding, < 1 cm parenchymal depth	2
	II	Hematoma: subcapsular, nonexpanding, 10–50% surface area; intraparenchymal, nonexpanding, < 10 cm in diameter	2
		Laceration: capsular tear, active bleeding, 1–3 cm parenchymal depth, < 10 cm in length	2
	III	Hematoma: subcapsular, > 50% surface area, expanding; ruptured subcapsular hematoma with active bleeding; intraparenchymal, > 10 cm or expanding	3
		Laceration: > 3 cm parenchymal depth	3
	IV	Hematoma: ruptured intraparenchymal hematoma with active bleeding	4
		Laceration: parenchymal disruption involving 25–75% of hepatic lobe or 1–3 Couinaud segments within a single lobe	4
	V	Laceration: parenchymal disruption involving > 75% of hepatic lobe or > 3 Couinaud segments within a single lobe	5
		Vascular: juxtahepatic venous injuries (i.e., injuries to retrohepatic vena cava or central major hepatic veins)	5
	VI	Vascular: hepatic avulsion	5
Extrahepatic biliary tree*	I	Gallbladder contusion/hematoma	2
		Portal triad contusion	2
	II	Partial gallbladder avulsion from liver bed; cystic duct intact	2
		Laceration or perforation of gallbladder	2
	III	Complete gallbladder avulsion from liver bed	3
		Cystic duct laceration	3
	IV	Partial or complete right or left hepatic duct laceration	3
		Partial common hepatic duct or common bile duct laceration (< 50%)	3
	V	> 50% transection of common hepatic duct or common bile duct	3–4

elevating the right costal margin with a large Richardson retractor. Further exposure can be achieved with mobilization, which requires division of the right triangular and coronary ligaments. In dividing the superior coronary ligament, care must be taken not to injure the lateral wall of the right hepatic vein; in dividing the inferior coronary ligament, care must be taken not to injure the right adrenal gland (which is vulnerable because it lies directly beneath the peritoneal reflection) or the retrohepatic vena cava. When the ligaments have been divided, the right hemiliver can be rotated medially into the surgical field. Mobilization of the left hemiliver poses no unusual problems other than the risk of injury to the left hepatic vein, the left inferior phrenic vein, and the retrohepatic vena cava.

If wide exposure of the junction of the hepatic veins and the retrohepatic vena cava is necessary, the midline abdominal incision can be extended by means of a median sternotomy. The pericardium and the diaphragm can then be divided toward the center of the inferior vena cava, minimizing injury to the phrenic nerve. This combination of incisions provides

superb exposure of the hepatic veins and the retrohepatic vena cava while avoiding injury to the phrenic nerves.

Temporary Control of Hemorrhage

Temporary control of hemorrhage is essential for two reasons. First, during treatment of a hepatic injury, ongoing hemorrhage may pose an immediate threat to the patient's life, and temporary control gives the anesthesiologist time to restore the circulating volume before further blood loss occurs. Second, bleeding sites other than the liver are common with both blunt and penetrating trauma, and if the liver is not the highest priority, temporary control of hepatic bleeding permits attention to other life-threatening injuries. The most useful techniques for the temporary control of hepatic hemorrhage are manual compression, perihepatic packing, and the Pringle maneuver.

Manual compression of the liver with laparotomy pads will control the majority of parenchymal hemorrhage [see Figure 5].^{17,18} Manual compression is best suited for immediate attempts to prevent exsanguination and for periodic

Figure 2 Contrast extravasation (arrows), indicating arterial hemorrhage, can be intraparenchymal (a, b) or intraperitoneal (c, d).

evaluation of bleeding sites during a complex procedure. The goal of this technique is to reapproximate the lacerated edges of the liver to their preinjury conformation.

Perihepatic packing with carefully placed laparotomy pads is capable of controlling hemorrhage from almost all hepatic injuries.¹⁹ The right costal margin is elevated, and the pads are strategically placed over and around the bleeding site [see Figure 6]. Additional pads should be placed between the liver,

diaphragm, and anterior chest wall until the bleeding stops. Ten to 15 pads may be required to control the hemorrhage from an extensive right lobar injury. Packing is not as effective for injuries to the left hemiliver, because with the abdomen open, there is insufficient abdominal and thoracic wall anterior to the left hemiliver to provide adequate compression. Two sequelae may be encountered with the packing of hepatic injuries. First, excessive packing compresses the

Figure 3 Nonoperative management of penetrating abdominal trauma (arrows) may be considered if the wound is isolated to the liver as documented by computed tomographic scan.

Figure 4 The anatomic divisions of the liver.

inferior vena cava, decreases venous return, and reduces left ventricular filling; hypovolemic patients may not tolerate the resultant decrease in cardiac output. Second, perihepatic packing forces the right diaphragm superiorly and impairs its motion; this may increase airway pressures and thus reduce tidal volume. If the patient has persistent bleeding despite packing, injuries to the hepatic artery, portal vein, and retrohepatic vena cava should be considered.

The Pringle maneuver,²⁰ which is the occlusion of the portal triad using a vascular clamp, can help delineate the source of hemorrhage and provide temporary control [see Figure 7]. We prefer to manually tear the lesser omentum and place the clamp from the patient's left side while guiding the posterior blade of the clamp through the foramen of Winslow with the aid of the left index finger. The advantages of this

approach are as follows: (1) it avoids injury to the hepatic pedicle structures, (2) it includes any aberrant or accessory hepatic arteries, and (3) the handle of the clamp sits over the stomach rather than the right lobe of the liver, hence providing better visualization and access. The length of time that a Pringle maneuver can remain in place without causing irreversible ischemic damage to the liver is unpredictable. Although cases in which a Pringle maneuver has been applied for more than 60 minutes without appreciable hepatic damage have been reported, the goal of warm ischemia time should be less than 30 minutes. An alternative is to release the Pringle maneuver intermittently to allow temporary revascularization. Ideally, one should attempt to perfuse the liver every 15 minutes for 5 minutes. Identification of the source of recurrent massive hemorrhage is clarified with application

Figure 5 Manual compression, with cooptation of the liver edges, temporarily controls blood loss in hypovolemic patients until the circulating blood volume can be restored.

of the Pringle maneuver; hemorrhage from hepatic artery and portal vein injuries should halt with the application of a vascular clamp across the portal triad (including accessory hepatic arteries), whereas hepatic veins and retrohepatic vena caval bleeding will continue.

Other, less commonly used techniques for hemorrhage control include the application of a tourniquet or a liver

clamp. A 2.5 cm Penrose drain may be used as a tourniquet; once the bleeding hemiliver is mobilized, the Penrose drain is wrapped around the liver near the anatomic division between the left hemiliver and the right hemiliver. The drain is stretched until hemorrhage ceases, and tension is maintained by clamping the drain. Unfortunately, tourniquets are difficult to use: they tend to slip off or tear through the parenchyma if placed over an injured area. An alternative is the use of a liver clamp; however, the application of such devices is hindered by the variability in the size and shape of the liver. We have not had consistent success with either of these methods.

To control hemorrhage from juxtahepatic venous injuries not controlled with perihepatic packing, complex interventions may be required to achieve hepatic vascular isolation. Three techniques that have been employed include (1) use of venovenous bypass with hepatic vascular isolation using clamps on the suprarenal vena cava and the suprahepatic vena cava, (2) the atriocaval shunt, and (3) the Moore-Pilcher balloon shunt. All techniques are performed with an associated Pringle maneuver. Of the three techniques, venovenous bypass is currently used by the authors.

Venovenous bypass²¹ offers several theoretical advantages in the trauma arena: it does not require systemic heparinization, it maintains good venous return to the heart, and it potentially allows decompression of the portal system to minimize bowel edema and avoid the reperfusion of toxic gut-derived products of ischemia. Venovenous bypass is accomplished by placing an 18 French catheter in the inferior vena cava via the femoral vein and a second 12 French catheter in the superior mesenteric vein via the inferior mesenteric vein [see Figure 8]. A centrifugal pump (Biomedicus pump,

Figure 6 Perihepatic packing is effective in managing the majority of parenchymal injuries. Multiple laparotomy pads are placed between the liver and diaphragm, followed by packs underneath the liver as seen on this sagittal illustration (a) and intraoperative picture (b).

Figure 7 The Pringle maneuver. The portal triad is occluded by guiding the posterior blade of the clamp through the foramen of Winslow with the aid of the left index finger.

Bio-Medics, Inc., Minneapolis, MN) withdraws blood from these veins and pumps it into the superior vena cava through a third 22 French catheter placed in the internal jugular vein. Flow rates of 1 to 2 L/min are maintained by the pump technician, who should limit the risk of air embolus. Hepatic

Figure 8 Venovenous bypass permits hepatic vascular isolation with continued venous return to the heart. IMV = inferior mesenteric vein; IVC = inferior vena cava; SMV = superior mesenteric vein.

isolation is achieved by clamping the inferior vena cava just above the renal veins and in a suprahepatic position, followed by a Pringle maneuver using standard vascular clamps.

The atriocaval shunt was designed to achieve hepatic vascular isolation while permitting venous blood to enter the heart from below the diaphragm.²² To place the shunt, the suprarenal and suprahepatic vena cava are encircled, and a 36 French chest tube is passed into the cava from a purse-string-controlled hole in the right atrial appendage. A variation of the original atriocaval shunt has been the substitution of a 9 mm endotracheal tube for the large chest tube [see Figure 9]. Although this change may seem trivial, surrounding the suprarenal vena cava with a snare tourniquet is extremely difficult because exsanguinating hemorrhage must be controlled by posterior compression of the liver, which severely restricts access to that segment of the vena cava. A historical alternative to the atriocaval shunt is the Moore-Pilcher balloon, which is no longer commercially available.²³ This device was inserted through the femoral vein and advanced into the retrohepatic vena cava. When the balloon was inflated, the hepatic veins and vena cava were occluded,

Figure 9 An endotracheal tube can be adapted to become an atriocaval shunt by cutting proximal holes to allow flow of blood into the atrium.

thereby achieving vascular isolation. The catheter itself was hollow, and holes placed below the balloon permitted blood to flow into the right atrium from the inferior vena cava. Despite a theoretically easier approach, there was no documented improvement in survival with this balloon occlusion technique.²⁴

Even in experienced centers with readily available equipment, however, such techniques carry a mortality rate greater than 80%. Surgeons who attempt hepatic vascular isolation should be aware that none of the techniques provide complete hemostasis. Because of the technical challenge and high mortality associated with hepatic vascular isolation, there has been a recent trend to avoid a direct operative approach to the injured vessels. If massive venous hemorrhage is seen from behind the liver, and if reasonable hemostasis can be achieved with perihepatic packing, the patient can be transferred to the interventional radiology suite, where hemorrhages from arterial sources are embolized and stents are placed to bridge venous injuries.²⁵

DEFINITIVE MANAGEMENT OF INJURIES

Parenchymal Injuries

A number of effective methods for the definitive control of hepatic parenchymal hemorrhage have been developed. Minor lacerations may be controlled with manual compression applied directly to the injury site. Topical hemostatic techniques include electrocautery (set at 100), the argon beam coagulator (set at 100), microcrystalline collagen, thrombin-soaked gelatin foam sponge, fibrin glue, and BioGlue (BioForm Medical, San Mateo, CA). Suturing of the hepatic parenchyma with large, liver stitches is generally discouraged because of the obligatory hepatic necrosis but remains an effective hemostatic technique in selected cases. The preferred suture material is 2-0 chromic catgut attached to a large, blunt-tipped, curved needle; the large diameter prevents the suture from pulling through the Glisson capsule. If, however, the capsule of the liver has been stripped away by the injury, this technique is far less effective. Interrupted simple or horizontal mattress sutures are placed parallel to the edge of the laceration. When tying sutures, adequate tension is achieved when hemorrhage ceases or the liver blanches around the suture. This technique of placing large liver sutures controls bleeding through reapproximation of the liver laceration rather than direct ligation of bleeding vessels. Aggressive finger fracture to identify bleeding vessels followed by individual clip or suture ligation was advocated previously but currently has a limited role in hemostasis. Hepatic lobar arterial ligation may be appropriate for patients with recalcitrant arterial hemorrhage from deep within the liver and is preferable to a deep hepatotomy, particularly in unstable patients. Omentum can be used to fill large defects in the liver. The tongue of omentum not only obliterates potential dead space with viable tissue but also provides an excellent source of macrophages. Additionally, the omentum can provide buttressing support for parenchymal sutures. Perihepatic packing following hepatic artery ligation is associated with an increased risk of hepatic necrosis. Several studies have demonstrated that the use of Penrose or sump drains is associated with a greater risk of intra-abdominal sepsis when compared with those treated with closed suction drains or no

drains.²⁶ Closed drains, however, are indicated if bile is seen emanating from the liver.

Resectional débridement is indicated for peripheral portions of nonviable hepatic parenchyma. Except in rare circumstances, the amount of tissue removed should not exceed 25% of the liver. Resectional débridement is performed by means of the finger-fracture technique or a modified stapled technique and is appropriate for selected patients with grade III to grade V lacerations. Because additional blood loss occurs during removal of associated viable tissue, this procedure should be reserved for patients who are in sound physiologic condition and can tolerate additional blood loss.

The final alternative for patients with extensive injuries to one hemiliver is anatomic hepatic resection. In elective circumstances, anatomic hemihepatectomies can be performed with excellent results; however, in the setting of trauma, the mortality associated with this procedure exceeds 50% in most series. Consequently, hepatic resection is rarely performed in trauma patients, having been largely replaced by perihepatic packing. Nonetheless, there are two circumstances in which anatomic resection may still be a reasonable choice. The first is prompt resection in patients with extensive injuries of the left lateral section of the liver because there is a much smaller area of parenchyma to traverse compared with lobectomy. The second is delayed anatomic hemihepatectomy in patients whose hemorrhage has been controlled but whose left or right hemiliver is nonviable as a result of ligation or thrombosis of critical blood supply. Because of the large mass of necrotic liver tissue, there is a high risk of subsequent infection or persistent hyperinflammation, setting the stage for multiple organ failure (MOF). The necrotic hemiliver should be removed as soon as the patient's condition permits.

Portal Triad Vascular Injuries

Injuries of the portal triad vasculature must be addressed immediately to control potential massive hemorrhage and minimize hepatic reperfusion injury. In general, ligation from the celiac axis to the level of the common hepatic artery at the gastroduodenal arterial branch is tolerated as a result of extensive collaterals, but the proper hepatic artery should be repaired. The right or left hepatic artery, or, in urgent situations, the portal vein, may be selectively ligated; occasionally, lobar necrosis will necessitate delayed anatomic resection. If the right hepatic artery is ligated, cholecystectomy should also be performed. Initial control of vascular injuries is accomplished digitally by applying enough direct pressure to stop the hemorrhage. Sharp dissection is used to define the injury and mobilizes sufficient length for proximal and distal control. Heparinized saline (50 U/mL) is injected into the proximal and distal ends of the injured vessel to prevent clot formation on the exposed intima. Ragged edges of the injury site should be judiciously débrided using sharp dissection.

The type of operative repair is based on the extent of injury. Lateral suture repair is preferred for arterial injuries with minimal loss of tissue. If the vascular injury is a stab wound with clean transection of the vessels, a primary end-to-end anastomosis is done. If the injury is destructive, temporary intravascular shunting should be used to reestablish inflow

while preparing for definitive repair. Interposition grafts are used in such cases when end-to-end anastomosis cannot be accomplished without tension despite mobilization. For the hepatic artery, autogenous saphenous vein from the groin should be used because polytetrafluoroethylene (PTFE) grafts less than 6 mm have a prohibitive rate of thrombosis. The portal vein, however, can be bridged with a PTFE graft. Portal triad injuries may be complicated with enteric contamination from colon or small bowel injuries. There is natural reluctance to place artificial grafts in such circumstances, but graft infections are rare. Therefore, following the control of hemorrhage, bowel contamination is contained and the abdomen irrigated before placing PTFE grafts. Blunt avulsions of the portal structures are particularly problematic if located at the hepatic plate, flush with the liver; hemorrhage control at the liver can be attempted with directed packing or Fogarty catheters. If the avulsion is more proximal, flush with the border of the pancreatic body or even behind the pancreas, the body of the pancreas must be transected to gain access for hemorrhage control and vascular repair. Overall mortality in patients with portal triad injuries is greater than 50%, with mortality approaching 80% in patients with combined injuries.²⁷ With the majority of deaths related to exsanguination in the operating room or postinjury refractory shock in the ICU, early hemorrhage control is paramount.

Penetrating Injuries

Simple lacerations can often be managed with interrupted simple liver sutures of 0-chromic. Translobar penetrating injuries are particularly challenging because the bullet frequently traverses a major blood vessel and the extent of the injury cannot be visualized. Management options include intraparenchymal tamponade with a Foley catheter or balloon occlusion.²⁸ A homemade balloon can be fashioned by placing a red Robinson catheter inside a 1-inch Penrose drain, ligating each end of the drain [see Figure 10]. The

deflated balloon is then inserted into the bleeding tract, and, once positioned, a contrast agent is injected through the red Robinson catheter to fill the Penrose balloon. If control of the hemorrhage is successful, a stopcock or clamp is used to occlude the catheter and maintain the inflation. Another option for hemorrhage control, particularly for deep lacerations, is Foley catheter occlusion [see Figure 11]. Using a Foley catheter with a 30 cc balloon, the tip is placed deep within the tract; the balloon is inflated sequentially along the length of the tract until hemorrhage stops. If tamponade is successful with either modality, the balloon is left inflated for 24 to 48 hours followed by judicious deflation in the surgical ICU and removal at a second laparotomy. If recurrent hemorrhage occurs, selective angioembolization should be pursued. Hepatotomy, using the finger-fracture technique, with ligation of individual bleeders may occasionally be required. However, division of the overlying viable hepatic tissue may cause considerable blood loss in the coagulopathic patient.

Gallbladder and Extrahepatic Duct Injuries

Injuries to the gallbladder or extrahepatic ducts may occur in isolation or in combination with more complex hepatic injuries.^{1,2} Cholecystectomy is performed for injuries to the gallbladder and following operative ligation of the right hepatic artery. Injuries of the extrahepatic bile ducts are a challenge because of their small size and thin walls. Because of the proximity of other portal structures and the vena cava, associated vascular injuries are common. Small lacerations, with no loss or devitalization of adjacent tissue, can be treated by the insertion of a T tube through the wound or by lateral suture using an absorbable 6-0 monofilament. Virtually all transections, and any injury associated with significant tissue loss, will require a Roux-en-Y choledochojejunostomy. The anastomosis is performed using a single-layer, interrupted technique using 6-0 monofilament absorbable suture. To reduce anastomotic tension, the jejunum should be tethered to the areolar tissue of the hepatic pedicle or porta hepatis.

Figure 10 Penrose expansion into a balloon with injection of saline (arrows), as described by Poggetti and colleagues, effectively controls translobar penetrating wounds.²⁸

Figure 11 Using a Foley catheter with a 30 cc balloon can also effectively tamponade deep laceration following blunt or penetrating trauma.

Injuries to the major hepatic ducts may not be possible to repair under emergent circumstances. One approach is to intubate the duct for external drainage and attempt a repair when the patient recovers. Alternatively, the lobar duct can be ligated if the opposite lobe is normal and uninjured.^{27,29}

POSTOPERATIVE CARE

Patients undergoing perihepatic packing for extensive liver injuries are typically returned to the operating room for pack removal 24 to 36 hours after the initial injury. Earlier exploration may be indicated in patients with evidence of ongoing hemorrhage. Signs of rebleeding are a falling hematocrit, blood clots accumulating under the temporary abdominal closure device, and bloody output from the Jackson-Pratt drains placed under the abdominal Ioban covering (3M, St. Paul, MN); the magnitude of hemorrhage is reflected in transfusion requirements and refractory acidosis. Patients with hepatic ischemia, as a result of a prolonged intraoperative Pringle maneuver, have an expected elevation but subsequent resolution of their transaminases; alternatively, patients requiring hepatic artery ligation may develop hepatic necrosis. Although patients should be evaluated for potential infectious complications, patients with complex hepatic injuries frequently have intermittent “liver fever” for the first 5 postinjury days. If perihepatic drains were placed intraoperatively, the quantity and quality of output should be evaluated. Persistent bilious output should prompt investigation for a bile leak. Alternatively, abrupt cessation of drainage with an associated fever should prompt consideration for diagnostic imaging.

In general, outcome following vascular injuries of the portal triad is related to the early technical success of the operation. Following hepatic artery interposition grafting, the patient’s systolic blood pressure should not exceed 140 mm Hg for at least the first 72 hours postoperatively. Conversely, following hepatic artery ligation, hypotension should be avoided. Midline laparotomy wounds are inspected 48 hours postoperatively by removing the sterile surgical dressing. If a wound infection is identified—evidenced by erythema, pain along the wound, or purulent drainage—the wound should be

opened by removing skin staples. After ensuring that the midline fascia is intact with digital palpation, the wound is initially managed with wet-to-dry dressing changes.

MORTALITY AND COMPLICATIONS

Overall mortality for patients with hepatic injuries is approximately 10%. The most common cause of death is exsanguination, followed by MOF and intracranial injury. Complications following major hepatic trauma include delayed hemorrhage, bilomas, perihepatic abscesses, hepatic necrosis, arterial pseudoaneurysms, and various fistulae.^{15,16} In patients requiring perihepatic packing, postoperative hemorrhage is not unusual. Ideally, patients should undergo reexploration once their coagulopathy is corrected; however, unstable patients should be returned to the operating room emergently for evaluation and repacking. Alternatively, angioembolization is appropriate in select cases, particularly for central lesions.

The most common sequelae of hepatic trauma are biliary fistulas, complicating up to 20% of injuries.^{8,16,30} Clinical presentation includes abdominal distention, pain and tenderness on examination; intolerance of enteral feeding; and abnormal liver function tests. Bedside ultrasonography should be used liberally. Bilomas, loculated collections of bile, can have a variable clinical course. Small, sterile bilomas will eventually be reabsorbed, but larger fluid collections should be drained percutaneously [see Figure 12]. Bilomas may become infected, particularly after penetrating trauma, and should be treated much like any other intra-abdominal abscess. If operative drainage becomes necessary for loculated collections, a twelfth rib resection approach provides optimal drainage for posterior infections. Biliary ascites, attributable to the disruption of a major bile duct, often requires reoperation. If the patient was initially treated nonoperatively, a laparoscopic approach may be considered for abdominal washout and drain placement.³¹ Primary repair of the injured duct is unlikely to be successful and is rarely attempted. Endoscopic retrograde cholangiography should be relied on for both diagnosis and treatment³² [see Figure 12]. Occasionally, the ductal injury can be stented, with adjunctive sphincterotomy to reduce pressure within the biliary system.^{30,33} The vast majority of ductal injuries, particularly in patients managed nonoperatively, heal within 4 to 6 weeks. Patients undergoing hepatic artery ligation, either operatively or with angioembolization, may develop hepatic necrosis. Resectional débridement is indicated for the removal of peripheral portions of nonviable hepatic parenchyma.³⁴

Pseudoaneurysms are rare complications of patients with hepatic injuries. Given that hemorrhage from hepatic injuries is often treated without isolating individual bleeding vessels, arterial pseudoaneurysms may develop, with the potential for rupture. Rupture into a bile duct results in hemobilia, which is characterized by intermittent episodes of right upper quadrant pain, upper gastrointestinal hemorrhage, and jaundice. If the aneurysm ruptures into a portal vein, portal venous hypertension with bleeding esophageal varices may occur. Either scenario is best managed with hepatic arteriography and embolization.^{35,36} Biliovenous fistulae, causing jaundice as a result of rapid increases in serum bilirubin levels, should

Figure 12 A biloma, evident on a computed tomographic scan (a), with an associated right hepatic duct injury evident on endoscopic retrograde cholangiography (b).

be treated with endoscopic retrograde cholangiopancreatography and sphincterotomy.³⁷ Rarely, a biliary fistulous communication will form with intrathoracic structures in patients with associated diaphragm injuries, resulting in a bronchobiliary or pleurobiliary fistula. As a result of the pressure differential between the positive biliary tract and the negative pleural cavity, the majority require operative closure. Occasionally, endoscopic sphincterotomy with stent placement will effectively address the pressure differential, and the pleurobiliary fistula will close spontaneously.

Injuries to the Spleen

The spleen is the second most commonly injured abdominal organ in blunt trauma patients. Historical studies have reported a 10% mortality with all splenic injuries; however, isolated splenic injury mortality is less than 1%. The mechanisms of injury are similar to those seen with liver injuries: motor vehicle collisions, autopedestrian accidents, and falls. Similar to penetrating trauma to the liver, stab wounds to the spleen typically result in direct linear tears, whereas gunshot wounds result in significant cavitory injuries.

Until the 1970s, splenectomy was considered mandatory for all splenic injuries. Recognition of the immune function of the spleen refocused efforts on splenic salvage in the 1980s.^{38,39} Following success in pediatric patients, NOM of splenic injuries was adopted in the adult population and has become the prevailing strategy for blunt splenic trauma.⁴⁰

INITIAL EVALUATION AND INJURY GRADING

Addressing the patient's ABC's, examining the patient's abdomen, and performing adjunctive imaging with FAST and CT are the initial steps of diagnosing a patient's splenic injury. Hypotension with a positive FAST scan should prompt emergent laparotomy. For patients with an identified blunt splenic injury on a CT scan, the injury should be graded

according to the AAST injury grading scale [see Table 1].³ Similar to liver injuries, the grade of splenic injury predicts failure rates and complication rates of NOM. Other findings that should be searched for on a CT scan include contrast extravasation (is the contrast blush contained within the spleen, or does it spill into the peritoneum?), the amount of intra-abdominal hemorrhage (is it isolated to the splenic fossa, or does blood extend into the pelvis?), and the presence of pseudoaneurysms [see Figure 13].

NONOPERATIVE MANAGEMENT

Indications for Nonoperative Management

NOM of solid-organ injuries is pursued in hemodynamically stable patients who do not have overt peritonitis or other indications for laparotomy.^{41–45} There is no age cutoff for patients for the NOM of solid-organ injuries.^{46,47} High-grade injuries, a large amount of hemoperitoneum, contrast extravasation, and pseudoaneurysms are not absolute contraindications for NOM; however, these patients are at high risk for failure.^{48–51} The identification of contrast extravasation as a risk factor for failure of NOM led to liberal use of angioembolization. The true value of angioembolization in splenic salvage has not been rigorously evaluated. Patients with intraparenchymal splenic blushes who are otherwise asymptomatic may be considered for a period of observation rather than empiric angioembolization⁵²; it is thought that the contained hemorrhage within the splenic capsule may result in tamponade of the bleeding [see Figure 14].

It is clear, however, that 20 to 30% of patients with splenic trauma deserve early splenectomy and that failure of NOM often represents poor patient selection.^{53,54} In adults, indications for prompt laparotomy include initiation of blood transfusion within the first 12 hours considered to be secondary to the splenic injury or hemodynamic instability. In the pediatric

Figure 13 Findings on imaging that are associated with failure of nonoperative management for splenic injuries: contrast extravasation or “blush” (arrow) (a), intra-abdominal hemorrhage extending into the pelvis (b), and pseudoaneurysms (c).

Figure 14 Intraparenchymal splenic blush (arrows) noted on an initial computed tomographic scan (a, b) may resolve following a period of close observation (c).

population, blood transfusions up to half of the patient’s blood volume are used prior to operative intervention. Following the first 12 postinjury hours, indications for laparotomy are not as black and white. Determination of the patient’s age, comorbidities, current physiology, degree of anemia, and associated injuries will determine the use of transfusion alone versus intervention with either embolization or operation. Unlike hepatic injuries, which rebleed in 24 to 48 hours, delayed hemorrhage or rupture of the spleen can occur up to weeks following injury. Algorithms for the management of pediatric splenic injuries exist,⁵⁵ and the patient’s physiologic status is the key determinant. Rapid mobilization in patients who are hemodynamically stable with a stable hematocrit and no abdominal pain is generally successful. Overall, nonoperative treatment obviates laparotomy in more than 90% of cases.

Follow-up Imaging

Out of concern over the risk of delayed hemorrhage or other complications, follow-up CT scans have often been recommended; unfortunately, there is no consensus as to when or even whether they should be obtained. Patients with grade I or II splenic injuries rarely show progression of the lesion or other complications on routine follow-up CT scans;

it is reasonable to omit such scans if patients’ hematocrits remain stable and they are otherwise well. Patients with more extensive injuries often have a less predictable course, and CT may be necessary to evaluate possible complications. Routine CT before discharge, however, is unwarranted. Outpatient CT, however, in patients who participate in vigorous or contact sports should be performed at 6 weeks to document complete healing before resuming those activities. A more convenient and less expensive alternative to follow-up CT is ultrasonographic monitoring of lesions.

OPERATIVE EXPOSURE AND HEMORRHAGE CONTROL

In penetrating abdominal injuries not suitable for NOM and in blunt abdominal injuries when NOM is contraindicated or has failed, exploratory laparotomy is performed.

To ensure safe removal or repair, the spleen should be mobilized to the point where it can be brought to the surface of the abdominal wall without tension. An incision is made in the peritoneum and the endoabdominal fascia, beginning at the white line of Toldt along the descending colon and continuing cephalad 1 to 2 cm lateral to the posterior peritoneal reflection of the spleen; this plane of dissection is continued superiorly until the esophagus is encountered [see Figure 15a]. Posteriorly, blunt dissection is performed to

Figure 15 The first step in mobilizing the spleen is to make an incision in the peritoneum and the endoabdominal fascia, beginning at the inferior pole and continuing posteriorly and superiorly (a). The correct plane of dissection is between the pancreas and Gerota fascia (b).

mobilize the spleen and pancreas as a composite away from Gerota fascia and up and out of the retroperitoneum; this posterior plane may be extended to the aorta if necessary [see Figure 15b]. Additionally, the attachments between the spleen and the splenic flexure of the colon may be divided to avoid avulsion of the inferior splenic capsule. Care must be taken not to pull on the spleen; otherwise, it will tear along the posterior peritoneal reflection, causing significant hemorrhage. It is often helpful to rotate the operating table 20° to the patient's right so that the weight of the abdominal viscera facilitates viscera retraction. Any ongoing hemorrhage from the splenic injury may be temporarily controlled with digital occlusion of the splenic hilar vessels. Once mobilization is complete, the spleen can be repaired or removed without any need to struggle to achieve adequate exposure.

DEFINITIVE MANAGEMENT OF INJURIES

Splenic injuries are treated operatively by splenectomy, partial splenectomy, or splenic repair (splenorrhaphy), based on the extent of the injury and the physiologic condition of the patient. Splenectomy is indicated for hilar injuries, pulverized splenic parenchyma, or any grade II or higher injury in a coagulopathic or multiply injured patient. We

employ autotransplantation of splenic implants [see Figure 16] for partial immunocompetence in younger patients.⁵⁶ Drains are not used. Partial splenectomy can be employed in patients in whom only the superior or inferior pole has been injured. Hemorrhage from the raw splenic edge is controlled with a horizontal mattress suture, with gentle compression of the parenchyma [see Figure 17]. Similar to hepatic injuries, splenorrhaphy techniques to achieve hemostasis include topical agents (electrocautery, argon beam coagulation, thrombin-soaked gelatin foam sponge, fibrin glue, BioGlue), enveloping the injured spleen in absorbable mesh, and pledgeted suture repair.

POSTOPERATIVE CARE AND COMPLICATIONS

Enthusiasm for splenic salvage was driven by the rare but often fatal complication of overwhelming postsplenectomy sepsis (OPSS). OPSS is caused by encapsulated bacteria, *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*, which are resistant to antimicrobial treatment. In patients undergoing splenectomy, prevention against these bacteria is provided via vaccines administered optimally at 14 days but definitely prior to hospital discharge.⁵⁷ Vaccines to be administered include Pneumovax (Merck & Co.,

Figure 16 Autologous splenic transplantation is performed by placing sections of splenic parenchyma, $40 \times 40 \times 3$ mm in size, into pouches in the greater omentum.

Figure 17 Splenorrhaphy is performed using interrupted mattress sutures through pledgets along the raw edge of the spleen.

Inc., Whitehouse Station, NJ), Menactra (Sanofi Pasteur, Swiftwater, PA), and Fluvirin (Novartis, East Hanover, NJ). Revaccination remains open to debate, but some argue for revaccination every 6 years.

An immediate postsplenectomy increase in platelets and white blood cells (WBCs) is normal; however, beyond postoperative day 5, a WBC count above $15,000/\mu\text{L}$ and a platelet to WBC ratio less than 20 are highly associated with sepsis and should prompt a thorough search for underlying infection.^{58,59} A common infectious complication following splenectomy is a subphrenic abscess, which should be

managed with percutaneous drainage. Following splenectomy or splenorrhaphy, postoperative hemorrhage may be attributable to loosening of a tie around the splenic vessels, a missed short gastric artery, or recurrent bleeding from the spleen if splenic repair was used. Additional sources of morbidity include a concurrent but unrecognized iatrogenic injury to the pancreatic tail during rapid splenectomy, resulting in pancreatic ascites or fistula.

Injuries to the Diaphragm

In cases of blunt trauma to the diaphragm, the injury is on the left side 75% of the time, presumably because the liver diffuses some of the energy on the right side. Blunt diaphragmatic injuries result in a linear tear in the central tendon, whereas penetrating injuries are variable in size and location depending on the weapon. With blunt, and occasionally with penetrating, injuries, the diagnosis is suggested by an abnormality of the diaphragmatic shadow on a chest radiograph [see Figure 18]. In patients without clear imaging results in the trauma bay, a CT scan may identify a diaphragmatic injury.

Regardless of the etiology, acute injuries are repaired through an abdominal incision or with thoracoscopy or laparoscopy. Following delineation of the injury, the chest should be evacuated of all blood and particulate matter, and tube thoracostomy should be placed if not previously done. Using Allis clamps to approximate the diaphragmatic edges, the defect is closed with a running No. 1 polypropylene suture [see Figure 19]. Occasionally, large avulsions or shotgun wounds with extensive tissue loss will require polypropylene mesh or AlloDerm (LifeCell, Branchburg, NJ) to bridge the defect. Alternatively, transposition of the diaphragm cephalad one to two intercostal spaces may allow repair without undue tension.⁶⁰

Financial Disclosures: None Reported

Figure 18 Left diaphragm ruptures are evident with the gastric bubble located in the left hemithorax (a), whereas right-sided ruptures present with the appearance of an elevated hemidiaphragm (b). Computed tomography may be used in questionable cases to better identify the injury (c).

Figure 19 Using Allis clamps to approximate the diaphragmatic edges, the defect is closed with a running No. 1 polypropylene suture.

8 INJURIES TO THE STOMACH, SMALL BOWEL, COLON, AND RECTUM

Jordan A. Weinberg, MD, FACS, and Timothy C. Fabian, MD, FACS

Hollow viscus injury is most commonly the result of penetrating abdominal trauma. It is relatively infrequent in the setting of blunt trauma: in one multi-institutional analysis, only 1.2% of blunt trauma admissions were associated with a hollow viscus injury.¹ Initial resuscitation of the patient with abdominal trauma is described in detail elsewhere. The diagnosis of hollow viscus injury remains a challenge in abdominal trauma patients, and subsequent evaluation is determined by the mechanism of injury. Regardless of the specific injury mechanism, however, the principles of operative management are the same.

Determination of Need for Operation

BLUNT TRAUMA

Hollow viscus injury after blunt trauma, although uncommon, can have serious consequences if the diagnosis is missed or delayed. In a multi-institutional study of 198 patients with blunt small bowel injury, delay of as little as 8 hours in making the diagnosis resulted in increased morbidity and mortality.² Mortality increased in parallel with time to operative intervention (< 8 hours to operation, 2% mortality; 8 to 16 hours, 9%; 16 to 25 hours, 17%; > 24 hours, 31%), as did the complication rate.

Particular consideration should be given to lap- and shoulder-restraint injuries, which may be associated with an increased risk of hollow viscus injury. The so-called seat-belt sign (i.e., ecchymosis of the abdominal wall secondary to the compressive force of the lap belt) is associated with a more than doubled relative risk of small bowel injury.³ Flexion-distraction fractures of the spine (Chance fractures) are also associated with lap-belt use, and the presence of such fractures should raise the index of suspicion for associated hollow viscus injury.

Physical examination findings such as abdominal tenderness or tachycardia may suggest the presence of hollow viscus injury. Reliability of the examination, however, may be compromised by distracting chest or long bone injury, closed head injury, spinal cord injury, or intoxication. Laboratory abnormalities including elevations in white blood cell (WBC) count, amylase, and/or lactic acid may also point toward the presence of hollow viscus injury, but are relatively nonspecific. Provided that the patient has suffered a low-risk mechanism of injury (such as a fall from standing or a low-speed motor vehicle collision), hollow viscus injury is extremely unlikely given a normal, reliable physical examination and normal laboratory results, and further investigation

along this path is unwarranted. However, the presence of abdominal complaints, an abnormal or nonreliable physical examination, abnormal laboratory results, or a high-risk mechanism of injury warrants further evaluation.

Ultrasonography is routinely performed early in the evaluation of blunt abdominal trauma. It is highly specific and moderately sensitive in identifying intra-abdominal fluid, the presence of which in a hemodynamically unstable patient is an indication for laparotomy (in that it strongly suggests the presence of significant intra-abdominal hemorrhage).⁴ Ultrasonography does not, however, reliably distinguish solid-organ injury from hollow viscus injury—a distinction that is critical for determining subsequent management (i.e., operative versus nonoperative) in a hemodynamically stable patient. Computed tomography (CT) and/or diagnostic peritoneal lavage (DPL) may help differentiate one type of injury from the other.

Helical (spiral) CT is currently the imaging modality of choice in stable patients who have undergone blunt abdominal trauma. Our experience indicates that it is useful for identifying blunt hollow viscus injury. In a review of over 8,000 CT scans performed to evaluate cases of blunt abdominal trauma, we found that the number of abnormal radiologic findings suggesting blunt injury to the bowel, the mesentery, or both [see Table 1] was correlated with the true presence of injury.⁵ A CT scan demonstrating a solitary abnormality was associated with a true positive rate of 36%, whereas a scan demonstrating more than one abnormality was associated

Table 1 Incidence of Findings Suggestive of Blunt Mesenteric and Bowel Injury in True Positive and False Positive CT Scans⁵

Finding	Incidence	
	True Positive CT Scans (%)	False Positive CT Scans (%)
Unexplained intraperitoneal fluid	74	79
Pneumoperitoneum	28	2
Bowel wall thickening	30	8
Mesenteric fat stranding	9	4
Mesenteric hematoma	19	19
Extravasation of luminal content	4	0
Extravasation of vascular content	9	0

CT = computed tomographic.

with a true positive rate of 83%. Unexplained intraperitoneal fluid (i.e., fluid appearing in the absence of solid-organ injury) was the most common radiographic finding associated with blunt bowel or mesenteric injury but often proved to be a false positive finding [see Table 1].

On the basis of this experience, we developed an algorithm for the evaluation of blunt hollow viscus injury in patients with unreliable physical examinations [see Figure 1]. If CT scanning demonstrates no suspicious findings, the patient is observed. No further diagnostic workup of hollow viscus injury is performed, and the duration of the observation period depends on both the overall condition of the patient and clinical judgment. It is worth noting that the 2003 multi-institutional review of 2,457 cases carried out by the Eastern Association for the Surgery of Trauma (EAST) reported a 13% incidence of blunt small bowel injury in patients with an initial negative CT scan. These results indicate that caution should be exercised in dismissing the presence of hollow viscus injury on the basis of a negative scan.³ This concern is echoed by our own institutional experience, in which the incidence of injury in patients with an initial negative CT scan was 12%.⁵

If CT demonstrates a solitary suspicious finding, DPL is performed for further evaluation. If DPL yields positive results (WBC count > 500 cells/ μ L, alkaline phosphatase level > 10 IU/L, or amylase level > 20 IU/L), exploratory laparotomy is performed. It must be kept in mind, however, that DPL results may be falsely negative or equivocal in the early period after trauma.⁶ This phenomenon may be attributable to a time lag between the intestinal perforation and the subsequent development of intraperitoneal leukocytosis. If a high degree of suspicion of hollow viscus injury remains even after a negative DPL result, DPL may be repeated. Alternatively, exploratory laparotomy may be performed. The choice between the two options is largely based on the individual surgeon's clinical judgment.

Figure 1 Algorithm outlining the evaluation of blunt injury to a hollow viscus. CT = computed tomographic; DPL = diagnostic peritoneal lavage.

If CT demonstrates multiple abnormalities, DPL is omitted from the workup and exploratory laparotomy is performed.

PENETRATING TRAUMA

Gunshot Wounds

Gunshot wounds to the abdomen generally necessitate exploratory laparotomy, given the high incidence of intra-abdominal injury. The exception to this rule is the case of a tangential wound that is believed to be traversing the soft tissues of the abdominal wall without entering the peritoneal cavity. In this scenario, we usually perform laparoscopy to look for peritoneal penetration. If the peritoneum has been violated, a laparotomy is done to permit systematic evaluation of the peritoneal cavity. If the peritoneum has not been violated, the operation may be terminated and the patient discharged after recovery from anesthesia, provided that there are no other extra-abdominal injuries necessitating hospital admission.

Stab Wounds

Stab wounds to the abdomen are associated with a lower incidence of intra-abdominal injury than gunshot wounds. Accordingly, there has been a shift toward selective management algorithms that rely on diagnostic tests, serial abdominal examination, or some combination of the two. When the peritoneum has obviously been penetrated (as with omental or bowel evisceration) or the patient presents with hemodynamic instability, we perform a laparotomy to evaluate the entire peritoneal cavity for organ injury. When it is unclear whether the peritoneum has been penetrated in a hemodynamically stable patient, we proceed with a definitive evaluation to rule out peritoneal violation. Anterior wounds (i.e., those anterior to the midaxillary line) are evaluated for fascial penetration by means of local wound exploration. In the emergency department, with sterile technique and local anesthesia, the wound is sharply extended to allow retraction of the subcutaneous tissue and visualization of the anterior fascia. If local wound exploration demonstrates the absence of fascial penetration, no further evaluation is necessary. If peritoneal violation is obvious on local wound exploration, we proceed with exploratory laparotomy. Often, however, fascial penetration is evident, but it is difficult to determine whether the peritoneum has been violated. In such cases, laparoscopy is performed in the operating room to look for peritoneal penetration. If peritoneal penetration is confirmed, we proceed with laparotomy.

Other centers have reported favorable experiences with expectant management of anterior stab wounds that penetrate the peritoneum.⁷⁻⁹ Patients without evidence of peritonitis are admitted and monitored with serial physical examinations. Development of abdominal pain, peritoneal signs, or hemodynamic instability heralds the presence of hollow viscus injury, and the patient should be taken to surgery immediately. Should the patient remain stable with an unremarkable physical examination, serial examinations may be discontinued after 24 hours.

The rationale for this approach is based on both the high incidence of nontherapeutic laparotomy for stab wounds that has been historically observed and the recognition that nontherapeutic laparotomy is not without risk, with reported

complication rates from 8 to 41%.^{10–12} Expectant management has been demonstrated to be relatively safe, and delayed intervention (within 24 hours) does not seem to portend the same risk as observed in blunt trauma.^{7–9,13} Nonetheless, it is inevitable that with the expectant approach, a significant injury on occasion will be missed. A prospective randomized trial comparing the safety and cost-effectiveness of mandatory laparotomy versus selective nonoperative management of abdominal stab wounds demonstrated lower morbidity (although not statistically significant) in the selectively managed group (8% versus 19%, $p = .26$).⁸ It is notable, however, that one patient in the selectively managed group developed empyema secondary to a missed diaphragmatic injury with associated gastric perforation.

Should expectant management be undertaken, it should be emphasized that appropriate patient selection is critical. Expectant management is not appropriate for the patient with an altered sensorium or unreliable physical examination. As noted (see above), we prefer to determine the presence of peritoneal penetration at the time of presentation and proceed with open exploration as indicated. The rationale for this approach is to avoid any delay in diagnosis of hollow viscus injury and to allow early discharge of patients with no peritoneal violation. Other centers have described the use of both CT and DPL to facilitate the decision to perform laparotomy, observe, or discharge the patient.^{14,15}

Wounds to the lower back or the flank (posterior to the midaxillary line), which carry a lower risk of intra-abdominal injury, are evaluated with CT, augmented by intravenous, oral, and rectal contrast studies. CT scanning has proved to be a reliable means not only of identifying posterior intraperitoneal violation but also of evaluating injury to retroperitoneal structures.^{16,17}

Operative Management of Injuries at Specific Sites

When hollow viscus injury is suspected, antibiotics with broad-spectrum aerobic and anaerobic coverage should be administered before the skin incision. If injury is confirmed, the antibiotics should be continued for a 24-hour period. The EAST Practice Management Guidelines Workgroup has reviewed the available evidence regarding perioperative antibiotic use in the trauma setting.¹⁸ Data from prospective studies clearly indicate that prolonging antibiotic administration beyond 24 hours provides no additional protection against surgical site infection (SSI).

Abdominal exploration is generally performed through a midline incision that is sufficiently extensive to permit evaluation of the entire peritoneal cavity. Once initial control of any significant bleeding has been obtained, the next step is to control any contamination from spilled gastrointestinal contents. Babcock clamps are useful for temporarily controlling contamination from bowel perforations without causing injury to the bowel wall. Inspection commences in a systematic fashion, with any holes in the bowel controlled as they are found. In the setting of penetrating injury, when an odd number of hollow viscus perforations is encountered, a diligent search for an additional perforation is essential. An odd number of perforations implies that one of the wounds is tangential (or that the projectile is intraluminal); this is a diagnosis of exclusion.

INJURIES TO THE STOMACH

Intraoperative evaluation of the stomach begins with full visualization of the anterior gastric surface from the pylorus to the esophagogastric junction. Proximal exposure is facilitated by incising the triangular ligament and retracting the left lateral section of the liver to the patient's right. The posterior aspect of the stomach is assessed by opening the gastrocolic ligament, which provides access to the lesser sac. Care must be taken to avoid injuring the vascular arcade of the greater curvature. While the stomach is elevated superiorly, the transverse colon is retracted inferiorly to expose the posterior gastric wall. Frequently, light adhesions between the posterior gastric wall and the retroperitoneum overlying the pancreas must be freed to provide full exposure. Alternatively, the greater omentum may be detached from its avascular attachment to the transverse colon to afford access to the lesser sac. Care must be taken to avoid placing excess tension on the greater curvature of the stomach and the short gastric vessels so as not to cause iatrogenic injury to the spleen. The greater and lesser curvatures should be closely inspected because the omental attachments may obscure an underlying gastric wound. Such inspection is particularly important in the setting of a small-caliber missile wound: the perforation can be remarkably small, and the serosal tissue damage in such cases is often subtle.

Treatment of a gastric injury is dictated by its severity [see Figure 2], which is classified according to the grading system developed by the American Association for the Surgery of Trauma (AAST) [see Table 2]. Intramural hematomas (grade I) are managed by means of unroofing and evacuation, followed by seromuscular closure with interrupted sutures. The great majority of gastric perforations are amenable to primary repair (grades II and III). In view of the propensity of the richly vascularized gastric wall to bleed at the site of injury, a two-layer technique is recommended to achieve adequate hemostasis. When the wound involves the pylorus, conversion to pyloroplasty to prevent stenosis is often beneficial. Suture repair of wounds at the cardioesophageal junction is reinforced by gastric fundoplication.

Some extensive wounds are not amenable to primary repair (grades IV and V). Such injuries include significant tissue loss or gastric devascularization and often are associated with major vascular injury as a consequence of the proximity of the major vessels and the force necessary to cause such a significant injury. Patients with grade IV or V injuries often do not survive long enough to undergo laparotomy; consequently, these extensive gastric wounds are rarely encountered. Grade IV injuries can usually be managed by means of a partial gastrectomy. Restoration of gastric outflow is accomplished with either a gastroduodenostomy or a gastrojejunostomy; the choice is dictated by the extent of the resection and the presence or absence of an associated duodenal or pancreatic injury. In the exceedingly rare event of complete gastric devascularization or destruction, a total gastrectomy is required; we have yet to encounter such a situation.

In fasting patients, the stomach harbors low numbers of bacteria because of its low pH. In trauma victims, however, who, it seems, often arrive with full stomachs, a more neutral pH and a higher bacterial count can be expected. If a gastric perforation with significant contamination is encountered,

Figure 2 Algorithm outlining the treatment of gastric injury.

secondary or delayed primary skin closure should be performed in view of the increased risk of SSI; this is particularly true when significant hemorrhage or associated injury is present, in which case, the rate of intra-abdominal abscess formation may be as high as 24%.¹⁹

INJURIES TO THE SMALL INTESTINE

Injury to the small intestine is evaluated intraoperatively by “running the bowel”: the small bowel and its mesentery are inspected in a systematic and comprehensive fashion from the ligament of Treitz caudad to the ileocecal valve. As active mesenteric bleeding is encountered, it is controlled by isolation and individual ligation of the bleeding vessels rather than by mass ligation of the mesentery, which may produce ischemia. Likewise, as bowel perforations are found, temporary control measures are rapidly initiated in an effort to prevent excessive or ongoing soilage. Once all bowel injuries are accounted for, the decision must be made whether to perform primary repair, resection of the injured segment, or some combination of the two. Primary repair of multiple injuries preserves bowel length and is generally preferred. At the discretion of the operating surgeon, resection of a segment containing multiple injuries may be performed to expedite the operation, provided that the amount of bowel to be resected is small enough that its loss would have only a negligible effect on digestive function.

In contemporary surgical practice, the patient with severe abdominal injuries is routinely managed with “damage control” or staged laparotomy. The damage control approach has evolved from a realization that the critically injured patient

often requires rapid, lifesaving bailout techniques to arrest hemorrhage and control enteric spillage to preempt the combined physiologic insult of the trauma and surgery from progressing to irreversible shock and death.²⁰ With respect to small bowel injuries managed in this scenario, reconstruction of intestinal continuity following bowel resection is not performed at the initial operation and is instead deferred to subsequent laparotomy following resuscitation of the patient (typically 24 to 48 hours following the initial operation). The damage control approach is employed to prevent or mitigate the development of acidosis, coagulopathy, and/or hypothermia secondary to major blood loss and resuscitation. This decision should be made early in the operative course and be based on the rapid recognition of injury patterns rather than the onset of physiologic derangement, which may herald the onset of irreversible shock.²⁰

Management of each wound is determined by its severity according to the AAST grading system [see Figure 3 and Table 2]. Small partial-thickness injuries (grade I) are managed by reapproximating the seromuscular layers with interrupted sutures. Small full-thickness wounds (grade II) are repaired with limited débridement and closure. Closure is performed in either one or two layers (we prefer a single-layer closure), and transverse closure is preferred to avoid luminal narrowing. Larger full-thickness wounds (grade III) may be repaired primarily if luminal narrowing can be avoided; otherwise, resection and anastomosis should be performed. Extensive wounds and wounds associated with devascularization (grades IV and V) are treated with resection and anastomosis. When mesenteric injury is encountered in the absence

Table 2 AAST Organ Injury Scales for Gastrointestinal Tract and Pancreas

Injured Structure	AAST Grade*	Characteristics of Injury	AIS-90 Score
Stomach	I	Intramural hematoma < 3 cm; partial-thickness laceration	2
	II	Intramural hematoma ≥ 3 cm; small (< 3 cm) laceration	2
	III	Large (> 3 cm) laceration	3
	IV	Large laceration involving vessels on greater or lesser curvature	3
	V	Extensive (> 50%) rupture; stomach devascularized	4
Duodenum	I	Single-segment hematoma; partial-thickness laceration	2; 3
	II	Multiple-segment hematoma; small (< 50% of circumference) laceration	2; 4
	III	Large laceration (50–75% of circumference of segment D2 or 50–100% of circumference of segment D1, D3, or D4)	4
	IV	Very large (75–100%) laceration of segment D2; rupture of ampullary or distal bile duct	5
	V	Massive duodenopancreatic injury; devascularization	5
Pancreas	I	Small hematoma without duct injury; superficial laceration without duct injury	2
	II	Large hematoma without duct injury or tissue loss; major laceration without duct injury or tissue loss	2; 3
	III	Distal transection or parenchymal laceration with duct injury	4
	IV	Proximal transection or parenchymal laceration involving ampulla	4
	V	Massive disruption of pancreatic head	5
Small bowel	I	Contusion or hematoma without devascularization; partial-thickness laceration	2
	II	Small (< 50% of circumference) laceration	3
	III	Large (≥ 50% of circumference) laceration without transection	3
	IV	Transection	4
	V	Transection with segmental tissue loss; devascularized segment	4
Colon	I	Contusion or hematoma; partial-thickness laceration	2
	II	Small (< 50% of circumference) laceration	3
	III	Large (≥ 50% of circumference) laceration	3
	IV	Transection	4
	V	Transection with tissue loss; devascularized segment	4
Rectosigmoid and rectum	I	Contusion or hematoma; partial-thickness laceration	2
	II	Small (< 50% of circumference) laceration	3
	III	Large (≥ 50% of circumference) laceration	4
	IV	Full-thickness laceration with perineal extension	5
	V	Devascularized segment	5

AAST = American Association for the Surgery of Trauma; AIS-90 = Abbreviated Injury Score, 1990 version.

*Advance one grade for multiple injuries, up to grade III.

of bowel injury, the associated bowel must be closely assessed for evidence of vascular compromise. If the bowel appears viable, the rent in the mesentery should be reapproximated after bleeding is controlled to prevent an internal hernia. If there is evidence of vascular compromise, bowel resection and anastomosis are indicated.

Determination of intestinal viability begins with assessment of the bowel's appearance. Adjunctive measures, such as the use of a handheld Doppler device or fluorescein infusion with Wood lamp illumination, may facilitate assessment of perfusion in segments where viability is questionable. We generally prefer to use a handheld Doppler device because it is easy to

use and is available at short notice in the operating room. A probe applied directly to the antimesenteric side of the bowel wall effectively detects the presence of arterial flow, which reliably demonstrates viability.

Small bowel anastomoses are usually handsewn in one or two layers, although stapling devices may also be employed. The choice of technique depends largely on surgeon preference. One multicenter retrospective study suggested that in the setting of trauma, stapled anastomoses had a higher complication rate than did sutured anastomoses²¹: overall, 13% of stapled anastomoses were associated with an intra-abdominal postoperative complication, compared with 5% of sutured

Figure 3 Algorithm outlining the treatment of small bowel injury.

anastomoses. Because this study did not separate small intestinal anastomoses from colonic anastomoses, it is unclear to what extent the results apply specifically to small bowel anastomoses. It is likely, however, that bowel edema contributes to staple line failure. If bowel edema is evident or anticipated, it may be prudent to perform a sutured anastomosis.

INJURIES TO THE COLON

In World War II, colostomy was mandatory for penetrating colon trauma because of the significant morbidity associated with anastomotic suture line dehiscence.²² In the ensuing years, experience with primary repair of penetrating colonic injuries in civilian settings suggested that primary repair could be performed safely and perhaps, in select cases, with less morbidity than colostomy.^{23,24} This suggestion was confirmed in the late 1970s by a randomized, prospective study that demonstrated significantly lower rates of intra-abdominal infection in patients treated with primary repair than in those treated with colostomy.²⁵ In that early trial, high-risk patients (i.e., those with shock, hemorrhage, associated injuries, delayed presentation, significant peritoneal soilage, destructive wounds of the colon, or loss of abdominal wall integrity) were excluded from randomization and treated with colostomy. Currently, there is less concern for such risk factors, and primary repair is gaining wider acceptance.²⁶

To direct management decisions, it is helpful to categorize penetrating colonic injuries as either nondestructive or destructive [see Figure 4].²⁷ Although blunt colonic injuries are considerably less common, we manage them in a similar fashion.

Nondestructive colonic injuries are defined as wounds that involve less than 50% of the bowel wall without devascularization. Such wounds account for approximately 80% of colon wounds and are amenable to primary suture repair with limited amounts of débridement. Sufficient data have been accumulated over the past 30 years to support primary repair as standard treatment for nondestructive colon wounds in the

absence of peritonitis, regardless of associated injuries or comorbid conditions. Evaluation of the available prospective and retrospective data indicates that the suture line failure rate for primary repair is approximately 1%, which is less than the rate generally reported for elective colon and rectal surgery. Mortality associated with suture line failure in this setting is uncommon. The favorable morbidity and mortality profiles, along with the inherent benefits of avoiding colostomy, support primary repair as standard therapy for nondestructive wounds. Partial-thickness lacerations (grade I) are repaired with inverting seromuscular sutures. Full-thickness lacerations (grade II) may be closed in one or two layers.

Figure 4 Algorithm outlining the treatment of colon injury.

Destructive colonic injuries are defined as wounds that completely transect the colon (grade IV) or involve tissue loss and devascularized segments (grade V). Optimal management of such wounds is less certain than optimal management of nondestructive wounds. Data from randomized and prospective trials demonstrate that resection and primary anastomosis can be performed safely.^{28–31} It should be kept in mind, however, that these results are derived from a relatively small number of reported cases. The retrospective data indicate a higher incidence of suture line failure and a significant incidence of associated mortality, suggesting that resection and primary anastomosis may not be the optimal treatment for all colonic wounds.²⁷

A 1994 report from our institution (University of Tennessee) concluded that patients with destructive colonic injuries who had comorbid medical conditions or transfusion requirements greater than 6 units of blood were at significantly higher risk for suture line breakdown when the wounds were managed with resection and primary anastomosis.³² Other reported risk factors that may direct the surgeon toward fecal diversion include a Penetrating Abdominal Trauma Index (PATI) score greater than 25, shock, and a delayed operation.³³ It is our practice to manage these patients as high-risk patients and perform fecal diversion. Diversion may be accomplished by means of either loop colostomy (with an open or closed distal stoma) or end colostomy (with a mucous fistula or closure of the rectal stump). The diversion technique is dictated by both surgeon preference and the nature of the colonic injury. In most civilian clinical practices, destructive wounds account for approximately 20% of all colon wounds encountered. Between 50 and 75% of destructive wounds do not have risk factors that prompt diversion. Thus, the overall diversion rate ranges from 5 to 10%. In our experience over the past several years, 90 to 95% of all colon wounds have been managed with primary repair or resection and anastomosis.

Destructive colon wounds managed in the context of damage control laparotomy are typically initially resected with the bowel left in discontinuity. On return to the operating room following resuscitation of the patient, the surgeon is faced with the decision to restore bowel continuity via a colonic anastomosis versus performing diversion via end colostomy or ileostomy. A third alternative is to perform anastomosis and proximally divert with a loop ileostomy. Relatively small clinical series concerning this scenario have suggested that delayed anastomosis in this context is relatively safe.^{34,35} In the largest reported series to date (56 patients), however, a relatively high anastomotic leak rate (12%) was observed, and the authors recommended that delayed colonic anastomosis be performed with caution.³⁶ It is notable, however, that stoma construction may present its own problems in the open abdomen scenario as these patients often have significant abdominal wall and bowel edema, potentiating the risk for stoma-related complications such as retraction or ischemia/necrosis. In general, we recommend that in the setting of the open abdomen, fecal diversion should be considered on a case-by-case basis, balancing the risks of anastomotic complications against the challenge of a potentially difficult stoma.

The potential risk of postoperative SSI associated with colonic injury should be considered at the time of the initial

laparotomy. Retained bullets or other projectiles that have penetrated the colon or rectum may act as nidus for abscess formation and should be removed when it is technically feasible to do so. Approximately 10% of these retained missiles result in soft tissue infection or osteomyelitis.³⁷ Delayed primary or secondary skin closure is recommended.

If colostomy is performed, it will eventually have to be closed in most cases. The mortality associated with colostomy closure is low, but the reported morbidity has varied considerably, ranging from 5 to 25% in single-institution studies.^{38–40} We typically perform closure 2 to 3 months after hospital discharge to allow time for the resolution of the dense inflammatory adhesions that may form after laparotomy. Before closure, a contrast enema is obtained to confirm that no distal strictures or fistulas are present. Some surgeons maintain that early closure (within 2 weeks) is as safe as the traditional late closure (3 months), with a shorter operating time and less intraoperative blood loss, and suggest that it may also allow colostomy closure during the patient's initial hospitalization.⁴¹ To date, however, this practice has not garnered wide enthusiasm.

Occasionally, blunt abdominal trauma associated with lap-belt use results in a large deserosalization injury to the cecum and ascending colon or to the sigmoid colon. In such cases, the serosa may be reapproximated with interrupted silk sutures in an accordion-type fashion, provided that the lumen is not significantly compromised by the imbrication of the submucosa. It is likely that subclinical luminal narrowing occurs frequently after such repairs, of which we rarely see sequelae. If significant luminal narrowing is anticipated or the serosal disruption is extensive enough to preclude reapproximation, resection of the injured segment with primary anastomosis is indicated.

INJURIES TO THE RECTUM

Recognition of rectal injuries requires diagnostic vigilance. All patients with a penetrating wound to the pelvis, perineum, buttock, or upper thigh should be evaluated for rectal injury. Digital examination for the presence of rectal blood is mandatory, but the absence of blood does not definitively rule out injury. Rigid proctoscopy should be performed whenever there is any suspicion of rectal injury. In our most recent experience with penetrating rectal injuries, sensitivities for digital rectal examination and rigid proctoscopy were 51% and 78%, respectively.⁴²

It is our practice to classify rectal injuries according to anatomic criteria, which then dictate management [see Figure 5].^{43,44} The anterior and lateral sidewalls of the upper two thirds of the rectum are serosalized; injuries in this region are classified as intraperitoneal and are managed in the same manner as colonic injuries [see Figure 4]. The upper two thirds of the rectum posteriorly and the lower one third of the rectum circumferentially are not serosalized; injuries in these regions are classified as extraperitoneal.

Extraperitoneal wounds in the upper two thirds are usually amenable to exploration and suture repair. Fecal diversion is also performed as an adjunctive measure and may be accomplished with either loop or end colostomy. In select cases in which the wound is primarily intraperitoneal with minimal extraperitoneal involvement, diversion may be omitted.

Figure 5 Algorithm outlining the treatment of rectosigmoid or rectal injury.

Extraperitoneal wounds to the lower third of the rectum are usually explored and repaired, provided that the wound is easily accessible without risk to the associated neurovascular and genitourinary structures. Fecal diversion is recommended. Wounds that are difficult to reach are not explored and instead are managed with proximal fecal diversion and presacral drainage. Presacral drainage is performed with the patient in the lithotomy position [see Figure 6]. A curvilinear incision is made in the skin between the coccyx and the anus, and blunt dissection is employed to gain entry into the presacral space. Generally, we place one or two Penrose drains into this space and gradually withdraw them between postoperative days 5 and 7.

Whether presacral drainage is necessary is controversial. There is published prospective evidence to suggest that presacral drainage does not lessen morbidity⁴⁵; however, this study did not make a distinction between accessible and inaccessible extraperitoneal wounds. Our view is that for inaccessible extraperitoneal wounds, presacral drainage is required to prevent retroperitoneal abscess formation, which results from fecal contamination of a relatively closed space and can produce significant morbidity in the form of retroperitoneal infection that may also track downward into the thighs. Accessible extraperitoneal wounds that are explored and repaired become effectively intraperitonealized; thus, presacral drainage is not required for these injuries.

As emphasized (see above), a tangential gunshot wound is a diagnosis of exclusion. This point is of particular importance when the wound involves the rectum because mobilization and visualization may be limited by a narrow pelvis, a fat-laden mesorectum, and, in many cases, a patient who is unstable as a result of associated injuries. Although a solitary proximal rectal gunshot wound may truly be tangential (or the projectile may be intraluminal), an associated distal extraperitoneal wound is often present. After primary repair of the proximal wound, fecal diversion and presacral drainage should be performed, as with inaccessible extraperitoneal rectal injuries.

Distal rectal washout was initially advocated on the basis of experience gained during the Vietnam War.⁴⁶ In the majority of civilian studies since then, however, distal rectal washout has had no significant effect on morbidity.^{43,47–49} It may

Figure 6 Presacral drainage is provided through a curved incision midway between the anus and the tip of the coccyx. With blunt dissection, two fingers are inserted between the rectum and the hollow of the sacrum. Penrose drains are inserted and sutured to the skin.

be useful in cases of severe wound contamination or fecal impaction, but, in general, it does not seem to be an important adjunct to the management of rectal injuries. Typically, distal rectal washout involves lavage of the rectum distal to the injury with 3 to 6 L of irrigant via an irrigation tube placed into the distal limb of a loop colostomy. The irrigant may be normal saline, a genitourinary irrigant, or an antiseptic

solution. Digital rectal dilatation is performed to facilitate drainage of the irrigant. Care should be taken to protect the midline wound with a polyethylene or similar barrier to reduce the risk of wound contamination during the washout.

Financial Disclosures: None Reported

9 INJURIES TO THE PANCREAS AND DUODENUM

Gregory J. Jurkovich, MD, FACS

Duodenal and pancreatic injury continues to challenge the trauma surgeon. The relatively rare occurrence of these injuries, the difficulty in making a timely diagnosis, and high morbidity and mortality rates justify the anxiety these unforgiving injuries invoke. These issues also likely explain the hesitancy of many to address pancreatic injuries with operative intervention and the most recent literature exploring the options and consequences of nonoperative management.¹⁻³ Mortality rates for pancreatic trauma range from 9 to 34%, with a mean rate of 19%. Duodenal injuries are similarly lethal, with mortality rates ranging from 6 to 25%. Complications following duodenal or pancreatic injuries are alarmingly frequent, occurring in 30 to 60% of patients.⁴⁻⁶ Recognized early, the operative treatment of most duodenal and pancreatic injuries is straightforward, with low morbidity and mortality. Recognized late, these injuries result in a protracted, difficult clinical course, often ending in a devastating outcome.⁷⁻¹¹

History

An 1827 report of a traumatic transection of the pancreas as a result of a stagecoach wheel running over a patient is generally recognized as the first literature on pancreatic trauma.¹² By 1903, Mickulicz was able to identify 45 cases of pancreatic trauma in the literature, of which 21 involved penetrating and 24 blunt injuries.^{13,14} He noted that all 20 patients not operated on died, and 18 of the 25 (72%) who were operated on survived—a remarkable success for the time. Mickulicz recommended a thorough exploration through a midline incision, suture control for hemostasis, and the placement of drains in all cases, recommendations that still hold today.¹³ In 1930, Stern reviewed 62 reported cases of pancreatic trauma, in which 30 of the patients survived and 32 died.¹⁴ His treatment recommendations were essentially the same as Mickulicz's, although Stern perhaps foresaw the role of diagnostic peritoneal lavage in his recommendation to use "abdominal puncture" to aid in the diagnosis of pancreatic trauma.

The occurrence of complications was also noted early. In 1982, Kulenkampff reported what was likely a pancreatic pseudocyst following blunt trauma.¹⁵ In 1905, Korte reported a case of isolated pancreatic injury with total transection and resultant pancreatic fistula.¹⁶ The fistula closed spontaneously (as most do), and the patient survived. In 1946, Whipple reported that the catgut sutures used in and about the pancreas were likely to dissolve, leading to hemorrhage, fistula formation, duodenal leaks, and peritonitis; the use of silk was recommended.¹⁷

Wartime experience with pancreatic trauma emphasizes the high morbidity and mortality but also the infrequent

occurrence of this injury. There were only 5 case reports of pancreatic injury from the American Civil War, with an 80% mortality¹⁸; 5 reported cases from British troops in World War I, with an 80% mortality; 62 cases (of 3,154 abdominal injuries) reported by the 2nd Auxiliary Surgical Group in 1944 and 1945 during World War II, with a 56% mortality¹⁹; and 9 cases from the Korean War, with a 22% mortality.²⁰ More direct surgical management of pancreatic wounds also occurred in each of these wartime experiences.

Diagnosis

The two most important determinants of outcome following pancreatic injury are the status of the main pancreatic duct and the time from injury to definitive management of a ductal injury. This was probably first recognized and emphasized by Baker and colleagues in 1962.²¹ Two subsequent reviews of the experience with pancreatic trauma at the University of Louisville confirmed and emphasized the importance of determining the status of the pancreatic duct. Heitsch and colleagues found that resection of distal ductal injuries as opposed to drainage alone significantly lowered postoperative morbidity and mortality,²² and Smego and colleagues confirmed this observation one decade later by noting that pancreatic resection distal to the site of ductal injury resulted in a decrease in the mortality rate at that institution from 19 to 3%.²³ Our experience at Harborview Medical Center in Seattle supports this in that accurate determination of the status of the pancreatic duct with intraoperative pancreatography results in a decrease in complications from 55% to 15%.²⁴ Although improvements in image quality have been noted,²⁵ cross-sectional body imaging techniques currently used in the multitrauma patient (computed tomography [CT] of the abdomen) do not routinely have adequate sensitivity to assess the ductal status, and magnetic resonance imaging (MRI) is usually too unwieldy in the acute trauma patient.²⁶ Hence, the challenge remains in making an early determination of the status of the pancreatic duct.

The diagnostic techniques of most use in a patient with a possible pancreatic injury depend on the mechanism of injury, other indications for early laparotomy, and the time interval following the initial abdominal insult. Patients with clear indications for laparotomy need little or no preoperative evaluations directed at identifying a possible pancreatic injury as the diagnosis of pancreatic injury must be made intraoperatively. However, establishing the presence of pancreatic injury in those not requiring immediate laparotomy for hemorrhage or bowel perforation is a challenge made more difficult by the knowledge that a missed pancreatic duct injury has dire consequences.²⁷⁻³⁰

Although there are isolated reports of patients with complete ductal transection being asymptomatic for weeks to months to years following the initial injury,^{23,27,29,31} it is more common for patients with initially missed pancreatic injuries to manifest an abdominal crisis within a few days of their injury.³²⁻³⁴ The failure of physical signs and symptoms to develop promptly is related to the retroperitoneal location of the pancreas, pancreatic enzymes remaining inactive following an isolated injury, and decreased secretion of pancreatic fluid after injury. Early identification of a subtle pancreatic injury therefore requires a high index of suspicion, a carefully planned approach, and close observation.

A high index of suspicion is warranted in all patients with high-energy direct blows to the epigastrium. The classic examples are a crushed steering wheel with an adult driver and a handle bar injury in a child.^{35,36} The energy of impact results in a crushing of the retroperitoneal structures against the spine and typically transecting the pancreas at this point. Soft tissue contusion in the upper abdomen and disruption of the lower ribs or costal cartilage are physical findings that should suggest possible pancreatic injury. Epigastric pain out of proportion to the abdominal examination is often another clue to a retroperitoneal injury.

HYPERAMYLASEMIA

Although the highest concentration of amylase in the human body is in the pancreas, hyperamylasemia is not a reliable indicator of pancreatic trauma. In one series, only 8% of blunt abdominal injuries with hyperamylasemia had pancreatic injury.³⁷ Conversely, as many as 40% of patients with a pancreatic injury may initially have a normal serum amylase.^{38,39} In addition, there is evidence that isolated brain injury can cause elevated amylase⁴⁰ or lipase⁴¹ via an unclear central mechanism. Nonetheless, the presence of hyperamylasemia should heighten suspicion for pancreatic injury. The time between pancreatic injury and serum amylase determination may be critical. In a report of 73 patients with documented blunt injury to the pancreas, serum amylase was elevated in 61 patients (84%) and normal in 12 (16%).⁴² All 12 patients with a normal amylase were evaluated within 3 hours of injury. Patients with an elevated amylase were assayed 7 ± 1.5 hours after injury compared with 1.3 ± 0.2 hours after injury in those patients with normal serum amylase. These investigators concluded that serum amylase levels determined within 3 hours of injury are not diagnostic.

Our review of the available data led us to conclude that the sensitivity of serum amylase in detecting blunt pancreatic trauma varies from 48 to 85% and the specificity varies from 0 to 81%.⁵ The negative predictive value of serum amylase following blunt trauma is about 95%.^{38,39,43} Sensitivity and positive predictive value may improve if serum amylase is assayed more than 3 hours after injury. What this means is that 95% of patients with blunt trauma with a negative amylase will indeed not have a pancreatic injury. An elevated serum or peritoneal lavage effluent amylase does not necessarily confirm the presence of a pancreatic injury, but it does mandate further evaluation.

IMAGING STUDIES

Blunt abdominal trauma patients with hyperamylasemia who present with a reliable, benign abdominal examination

are carefully observed and serial amylase is remeasured after several hours. Persistent elevation or the development of abdominal symptoms is grounds for further evaluation, which may include abdominal CT scan, endoscopic retrograde cholangiopancreatography (ERCP), or surgical exploration. If the abdominal examination is initially equivocal or unreliable, hemodynamically stable patients with hyperamylasemia should undergo a dual-contrast (intravenous and oral) abdominal CT scan as part of the initial evaluation. If the patient subsequently develops abdominal symptoms or the amylase fails to normalize, a directed evaluation of the pancreas is warranted, either by repeat abdominal CT, ERCP, or surgical exploration.

Abdominal CT scans have a reported sensitivity and specificity of 70 to 80% in diagnosing pancreatic injury, although the accuracy of this examination is largely dependent on interpreter experience, the quality of the scanner, and the time from injury.⁴⁴⁻⁴⁶ The CT findings of pancreatic injury include direct visualization of a parenchymal fracture [see Figure 1], an intrapancreatic hematoma, fluid in the lesser sac, fluid separating the splenic vein and pancreatic body, thickened left anterior renal fascia, and retroperitoneal hematoma or fluid. These findings are often subtle, and rarely are they all present in one patient.⁴⁷ Some of the CT signs of pancreatic injury may not yet be apparent if the patient is examined immediately after injury, perhaps attributing to the reports of false-negative CT scans in up to 40% of patients with significant pancreatic injuries.⁴⁸ This, however, is not grounds for delaying a CT evaluation but is an argument for repeating a CT scan if symptoms persist.

Although ERCP has no role in the acute evaluation of the hemodynamically unstable patient, there has been a flurry of reports over the past decade regarding the utility of ERCP in diagnosing and managing pancreatic trauma. ERCP is currently the best imaging technique of the pancreatic duct and its divisions but usually requires anesthesia and is not readily or widely available. Most experience has been with ERCP in the late or missed diagnosis of pancreatic duct injury, occasionally with transducal stenting used to manage the injury, particularly in children.⁴⁹⁻⁵³ This is an evolving issue that will continue to foster investigations, but the principle of timely diagnosis and recognition and management of ductal injury remains.^{22,54} Early ERCP showing intact pancreatic ducts, including the secondary and tertiary radicals, without any extravasation permits nonoperative therapy if no associated injuries are present.⁵⁵ The difficulty in this management scheme is determining which patients warrant ERCP and getting the ERCP accomplished promptly.^{56,57}

MRI has emerged as a potential technique in the evaluation of the pancreatic duct in the earliest part of the 21st century.^{26,58} Although primarily used to date in elective circumstances, magnetic resonance pancreatography (MRCP) has been reported as a noninvasive alternative to determine the status of the main pancreatic duct in a small series of patients with pancreatic injury. To date, most reports suggest that MRCP is either unreliable or too unwieldy in the very acute phase after injury, but MRCP appears to be gaining increased interest in delayed diagnosis and management.⁵⁹ Further study of its sensitivity and specificity in this setting is warranted, but the initial enthusiasm appears to have been tempered.

Figure 1. Contusion to the body of the pancreas. Illustrated is the appearance of a contusion to the body of the pancreas overlying the vertebral column, as seen from the lesser sac (a). The pancreas is mobilized to determine whether a fracture is present and to assess the likelihood of a duct injury. This exposure is best accomplished by dissecting along the inferior border of the gland, dividing the inferior mesenteric vein if necessary, and reflecting the pancreas superiorly (b).

INTRAOPERATIVE EVALUATION

Classification of pancreatic injuries is based on the status of the pancreatic duct and the site of injury relative to the neck of the pancreas. Careful pancreatic inspection and injury classification are often complicated by the extent and severity of associated injuries and occasionally by the reluctance of the surgeon to mobilize retroperitoneal structures. Clues suggesting potential pancreatic injury include the injury mechanisms previously described, the presence of upper abdominal wall contusion or abrasion, and concomitant lower thoracic spine fractures. The presence of a upper abdominal central retroperitoneal hematoma, edema about the pancreatic gland and lesser sac, and retroperitoneal bile staining mandate thorough pancreatic inspection.

Inspection of the pancreas requires complete exposure of the gland. The initial steps in exposure are to open the lesser sac through the gastrocolic ligament just outside the gastroepiploic vessels. Carry this exposure far to the patient's left, fully opening the lesser sac and freeing up the transverse colon. The transverse colon is retracted downward and the stomach upward and anteriorly [see Figure 1]. Frequently, a few adhesions between the posterior stomach and the anterior surface of the pancreas need to be incised. A complete Kocher maneuver is required next to provide adequate visualization

of the pancreatic head and uncinate process. In addition, mobilization of the hepatic flexure of the colon (a frequently overlooked maneuver) greatly facilitates visualization and bimanual examination of the head and neck. Inspection of the tail of the pancreas requires exposure of the splenic hilum. If injury involves the tail of the pancreas, mobilization is achieved first by division of the peritoneal attachments lateral to the spleen and colon. The colon, spleen, and body and tail of the pancreas are then mobilized forward and medially by creating a plane between the kidney and the pancreas with blunt finger dissection. This maneuver permits bimanual palpation of the pancreas and inspection of its posterior surface.

It is worth noting that injuries to the major duct occur in perhaps 15 to 20% of pancreatic trauma. In our institution, we managed 193 pancreatic injuries over a 15-year time frame.⁴ Only 27 (14%) had grade III injuries and 10 (5%) grade IV or V injuries. In the 1970s and 1980s, penetrating wounds were documented as more likely to cause pancreatic duct injury,^{60,61} but more recent reviews have not substantiated that observation.^{4,62} Regardless of the mechanism, the majority of pancreatic duct injuries can be diagnosed by careful inspection of the tract of injury following adequate exposure. All penetrating wounds should be traced from their

entry point through the surrounding tissue to the point of exit or lodging of the missile. If the pancreas has been damaged by a knife or a bullet, it is necessary to determine the integrity of the major pancreatic duct. Most penetrating wounds to the margins of the gland can be inspected directly and duct integrity confirmed. However, penetrating wounds in the head or neck or central portion of the pancreas often require further evaluation. Occasionally, intravenous injection of 1 to 2 μ g of cholecystokinin pancreatozymin (1 to 2 mL of sincalide) may stimulate pancreatic secretions enough to localize an otherwise unrecognized major duct injury. The remaining few injuries may require the more elaborate investigative techniques, including intraoperative pancreatography (see below).

Minor blunt contusions or lacerations of the pancreatic substance usually do not require further evaluation of the pancreatic duct and are effectively managed with closed suction drainage. An intact pancreatic capsule, however, does not necessarily rule out complete division of the pancreatic duct, and, rarely, blunt impact to the pancreas can result in transection of the major duct without complete transection of the gland.²³ Establishing the status of the major ductal system under these circumstances remains an important step in determining therapy and in anticipating late morbidity and mortality. Routine performance of intraoperative pancreatography when proximal duct injury was suspected decreased the postoperative morbidity rate from 55% to 15% at our institution.²⁴

Intraoperative imaging of the pancreatic duct can be performed by one of three techniques: ERCP, direct open ampullary cannulation, or needle cholangiopancreatography. Intraoperative ERCP is cumbersome and often difficult to coordinate during an emergency operation, but it has been used and reported.⁶³ Duodenotomy and direct ampullary cannulation, or even transection of the tail of the pancreas and distal duct cannulation, have been reported as useful techniques in the past, but current perioperative imaging, improved exposure and direct visualization of the pancreas, and effective use of wide closed-suction drainage and postoperative ERCP have largely abolished the use of these very invasive diagnostic techniques of imaging the pancreatic duct.⁶⁴ Needle cholecystocholangiopancreatography remains a useful intraoperative adjunct in the evaluation of the pancreatic duct. This technique involves cannulating the gallbladder with an 18-gauge angiocatheter and injecting 30 to 75 mL of three-quarter-strength water-soluble contrast under fluoroscopic imaging. Clear images of the biliary tree are readily obtained, and in our experience, this technique is successful in imaging the pancreatic duct 64% (7 of 11) of the time.⁴ Contracture of the sphincter of Oddi with intravenous morphine may enhance the likelihood of pancreatic duct visualization. A cholecystectomy is not necessary following this procedure.

Classification of Pancreatic Injuries

Although a number of classification systems have been devised to catalogue pancreatic injuries,^{60,64,65} the American Association for the Surgery of Trauma (AAST) Committee on Organ Injury Scaling addresses the key issues of treatment of parenchymal disruption and major pancreatic duct status by focusing on the anatomic location of the injury for the more severe (grade III to V) injuries [see Table 1].⁶⁶ Table 1

also defines the Abbreviated Injury Scale (AIS) value that corresponds to the AAST grading system.⁶⁷ The AIS has undergone a revision in 1998 and again in 2005. These differences are important since most commercially available trauma registries use AIS coding. The AIS coding system is sponsored and owned by the Association for the Advancement of Automotive Medicine. Duct injuries have different management alternatives than distal duct and parenchymal injuries [see Figure 2]. Parenchymal contusions or lacerations with minimal or no parenchymal tissue loss and no ductal injury (grade I or II) need only be externally drained. Combined duodenal and pancreatic head injuries that include the major duct or ampulla require a combined pancreatoduodenectomy, commonly known as the Whipple procedure, but uncommonly required for trauma. The difficult decisions in managing pancreatic trauma involve patients with parenchymal disruption and major duct injury. By focusing on the anatomic location of the duct and parenchymal injury (proximal versus distal), this classification provides a useful management guide.

Treatment of Pancreatic Injuries

CONTUSIONS AND LACERATIONS WITHOUT DUCT INJURY

Minor pancreatic contusions, hematomas, and capsular lacerations (grade I) account for about 50% of all pancreatic injuries; lacerations of the pancreatic parenchyma without major ductal disruption or tissue loss (grade II) account for an additional 25% of pancreatic injuries. These injuries are the injury pattern commonly managed nonoperatively. If identified at operation, they require only hemostasis and adequate external drainage.^{2,68} No attempt should be made to repair capsular lacerations because closure may result in a pancreatic pseudocyst, whereas a controlled pancreatic fistula is usually self-limiting. Soft closed-suction drains (Jackson-Pratt) are preferred over Penrose drains or sump drains as intra-abdominal abscess formation is less likely, effluent is more reliably collected, and the excoriation of the skin at the exit site is significantly less with closed-suction drains.^{35,69,70} Drains are removed when the amylase concentrations in the drain are less than that of serum, generally within 24 to 48 hours. An international consensus group definition of pancreatic fistula is the persistence of any measurable volume of drain output on or after postoperative day 3 with an amylase content greater than three times serum amylase activity.⁷¹ As described below, there are three grades of pancreatic fistula complications [see Complications, below]. Drains are generally left in situ until there is no evidence of pancreatic leak.

Nutrition should be provided via the oral or gastric route as soon as possible. However, a prolonged gastric ileus or pancreatic complications may preclude standard gastric feeding in patients with severe injuries. Also, since most tube feeding formulas are high in fat and increase pancreatic effluent volume and amylase concentration, the low fat and higher pH (4.5) of elemental diets are preferred as they tend to be less stimulating to the pancreas.^{72,73}

DISTAL TRANSECTION AND DISTAL PARENCHYMAL INJURY WITH DUCT DISRUPTION

The anatomic distinction between proximal and distal pancreas is generally defined by the superior mesenteric

Table 1 AAST Organ Injury Scales for Pancreas and Duodenum

Injured Structure	AAST Grade*	Characteristics of Injury	AIS-90 Score	AIS-2005 Score
Pancreas	I	Small hematoma without duct injury; superficial laceration without duct injury	2	2
	II	Large hematoma without duct injury or tissue loss; major laceration without duct injury or tissue loss	2; 3	2
	III	Distal transection or parenchymal laceration with duct injury	3	3
	IV	Proximal [†] transection or parenchymal laceration involving ampulla	4	4
	V	Massive disruption of pancreatic head	5	5
Duodenum	I	Single-segment hematoma; partial-thickness laceration without perforation	2; 3	2
	II	Multiple-segment hematoma; small (< 50% of circumference) laceration	2; 4	2
	III	50–75% disruption (laceration) of segment D2 or 50–100% disruption of segment D1, D3, or D4	4	3
	IV	Very large (75–100%) laceration of segment D2; rupture of ampulla or distal CBD	5	4
	V	Massive duodenopancreatic injury; devascularization of duodenum	5	5

AAST = American Association for the Surgery of Trauma; AIS-90 = Abbreviated Injury Score, 1990 version; AIS-2005 = Abbreviated Injury Score, 2005 version; CBD = common bile duct.

*Advance one grade for multiple injuries, up to grade III.

[†]Proximal pancreas is to the patient's right of the superior mesenteric vein.

vessels passing behind the pancreas at the junction of the pancreatic head and body. Although there is no anatomic distinction in the gland itself between the head, body, or tail, this anatomic division is useful in estimating residual pancreatic endocrine and exocrine function. Innes and Carey have shown that a distal pancreatic resection at the portal vein removes an average of 56% (range 36 to 69%) of the gland by weight.⁷⁴ Since most blunt trauma pancreatic injuries occur at the spine, which is just to the patient's left of the portal vein as it crosses behind the pancreas, a "distal pancreatectomy" in this circumstance averages as a 56% gland resection. A resection at the common bile duct removes an average of 89% (range 64 to 95%) of the gland. Although reports of normal endocrine and exocrine function after 90% pancreatectomy do occur, every effort should be made, if possible, to leave at least 20% residual pancreatic tissue to minimize postoperative complications.^{75,76}

Distal parenchymal transection, particularly with disruption of the main pancreatic duct, is best treated by distal pancreatectomy. This is true in children and adults. CT, particularly if done more than 4 hours after the injury has occurred, is usually accurate enough to confirm complete transection. Operative intervention in this case is superior to nonoperative management in that the operation is definitive, the residual gland is adequate to preserve exocrine and endocrine function, and the recovery is relatively short. Nonoperative management is typically fraught with the complications of pseudocysts, abscess, prolonged and recurrent hospital admissions, and repetitive drainage procedures, including the technically challenging and invasive attempts at endoscopically traversing a transected distal duct.^{1,10,77}

If at celiotomy there is any concern regarding the status of the remaining proximal main pancreatic duct, intraoperative pancreatography should be performed through the open end of the proximal duct. If the remaining proximal duct is normal, the transected duct should be identified and closed with a direct "U"-stitch suture ligature with a nonabsorbable monofilament suture.⁷⁸ The parenchyma can be closed with the large (4.8 mm) TA-55 staple,^{78,79} but we find that this excessively crushes the residual pancreas, so we prefer mattress sutures placed through the full thickness of the pancreatic gland from anterior to posterior capsule to minimize leak from the transected parenchyma. Although most surgeons prefer nonabsorbable suture for pancreatic stump closure, one report suggests that a lower complication rate is obtained with absorbable polyglycolic acid suture to oversee the pancreatic stump.⁵⁴ A small omental patch can be used to buttress the surface, and a drain should be left near the transection line.

Concern for the possibility of postsplenectomy sepsis and subphrenic abscess formation following splenectomy has prompted several authors to describe distal pancreatectomy without splenectomy [see Figure 3]. The technical challenge in pancreatectomy with splenic salvage is in isolating and ligating the pancreatic branch vessels off the splenic vein and artery yet preventing injury to the splenic hilum and thrombosis of the splenic vein. Generous mobilization of the entire pancreatic gland and spleen is a prerequisite. An average of 22 tributaries of the splenic vein and seven branches of the splenic artery must be ligated.⁸⁰ One report suggests that this maneuver will add an average of 50 minutes (range 37 to 80 minutes) to the operative time.⁸¹ Patton and colleagues reported splenic salvage in 21 of 33 patients (64%) who

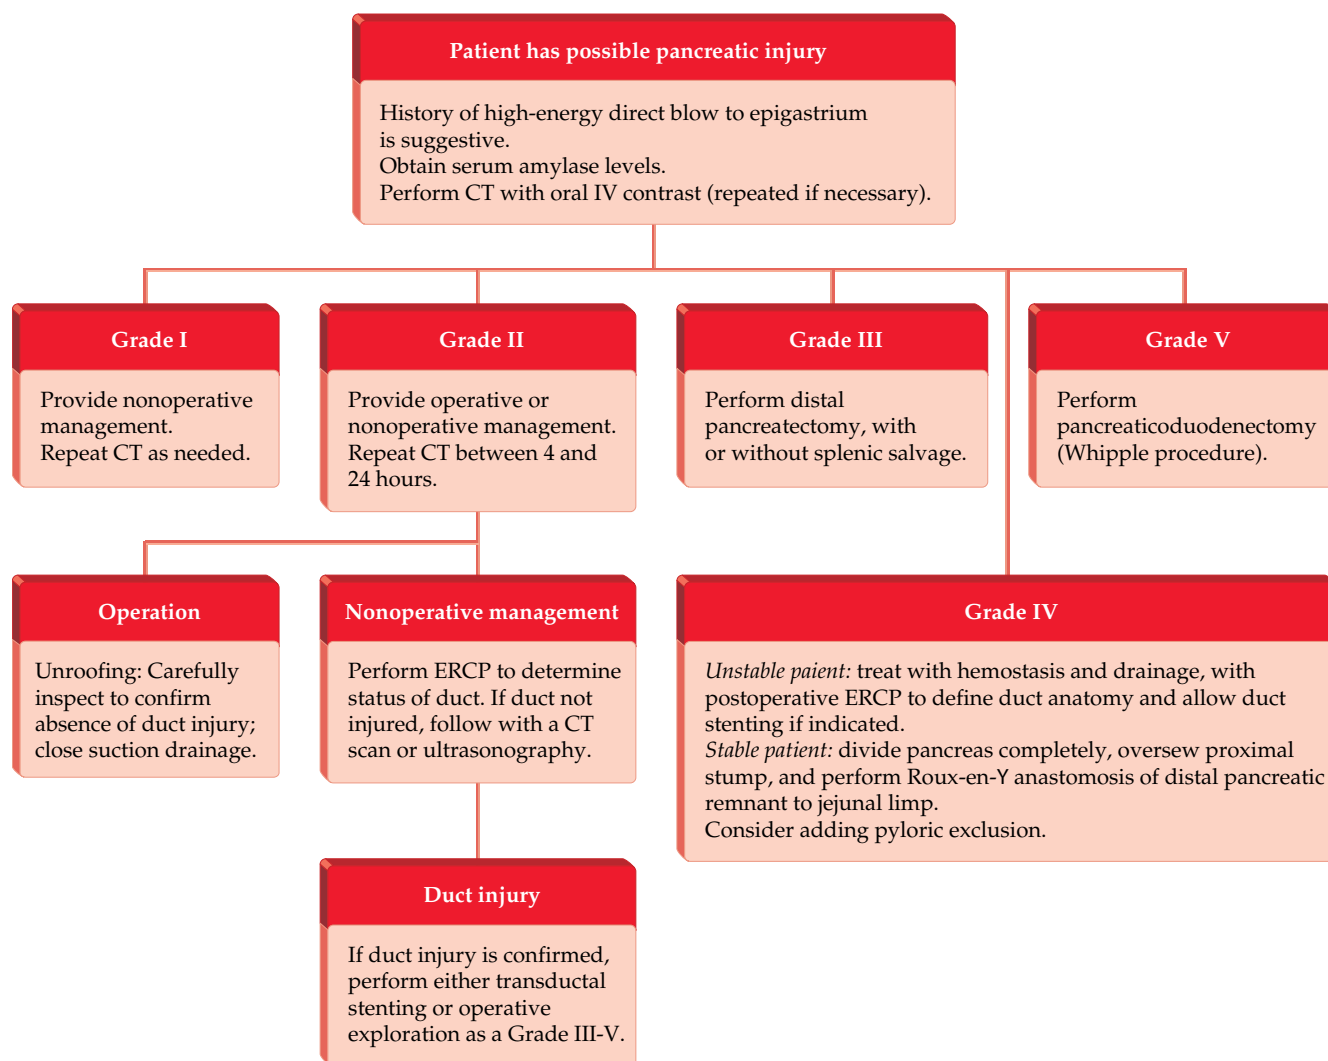

Figure 2. Treatment of pancreatic injury. Algorithm outlining the treatment of pancreatic injury. CT = computed tomography; ERCP = endoscopic retrograde cholangiopancreatography.

underwent distal pancreatic resection (8 blunt, 13 penetrating).³⁴ The increased operative time and potential blood loss incurred while performing pancreatectomy without splenectomy must be balanced against the slight risk of overwhelming postsplenectomy sepsis. The balance would seem to favor splenic salvage only when the patient is completely hemodynamically stable and normothermic and the pancreatic injury is isolated or present with only minor associated injuries.

PROXIMAL TRANSECTION OR INJURY WITH PROBABLE DUCT DISRUPTION

Injuries to the pancreatic head represent the most challenging management dilemmas. The key principles of immediate management are, in order, control bleeding, halt contamination, and define the anatomy of the injury. Effective management can only follow these steps. It is essential that the surgeon define the pancreatic duct anatomy in proximal pancreatic injuries. This can usually be accomplished by local inspection and exploration of the defect to determine the duct status. Techniques of intraoperative pancreatography

have been described above and are strongly recommended if local exploration alone is inadequate to determine the status of the main pancreatic duct. The only exception to this approach is the hemodynamic unstable patient with hypothermia, acidosis, and coagulopathy, in which case, simple damage control surgery is advised. Most experienced surgeons express reservations regarding performance of a duodenotomy to perform pancreatography, but a needle cholecystocholangiopancreatography can often image the pancreatic duct along with the distal common bile duct (64% in our experience).⁴ If this proves unsuccessful, then wide external drainage with several closed-suction drains should be performed with planned early postoperative ERCP (preferred), or MRCP should be the plan. If major proximal duct injury is confirmed by postoperative ERCP, pancreatic duct stenting rather than near-total pancreatectomy may be an option depending on local expertise.^{1,49,50,53} However, at least one report has had discouraging results with stenting, notable for long-term stricture development and acute sepsis.³⁰

Figure 3. Distal pancreatectomy with and without splenic salvage. Illustrated is distal pancreatectomy with salvage of the spleen (a) and without splenic salvage (b).

If the proximal duct is injured, but the ampulla and duodenum are spared (rare), two options are available. One option is extended distal pancreatectomy, resulting in subtotal removal of the gland. The proximal residual gland will drain into the duodenum in a normal fashion if the duct is intact. Wide external drainage of the residual pancreatic surface must be provided. We have not added pyloric exclusion or duodenal defunctionalization or diverticulization to this procedure, although others advocate its use in this circumstance.^{72,82} If there is concern that the residual proximal pancreatic tissue is inadequate to provide endocrine or exocrine function, the second option is to preserve the pancreatic tail distal to the injury using a Roux-en-Y pancreaticojejunostomy [see Figure 4]. This requires division of the pancreas at the site of injury, débridement of injured parenchyma, secure closure of the proximal duct and parenchyma,

and anastomosis of the open end of the divided distal pancreas to the Roux-en-Y jejunal limb. A review of 399 patients with pancreatic injury from four separate publications revealed that only 2 (0.5%) patients underwent Roux-en-Y drainage of the distal segment of a transected pancreatic gland.^{34,54,83,84} Although rarely employed and complicated by the need for a combination of pancreatic resection, pancreatic-jejunal anastomosis, and construction of the Roux-en-Y limb, this operation needs to be in the armamentarium of trauma surgeons.

The report by Patton and colleagues from Memphis, supported by the experience of University of Mississippi reported by Duchesne and colleagues, is compelling for the effectiveness of drainage alone rather than extended pancreatectomy, particularly for proximal pancreatic gland injury in which the duct status is unclear.^{2,34} In the Patton and

Figure 4. Roux-en-Y pancreaticojejunostomy. If a patient has a grade IV injury to the pancreatic head and there is concern regarding whether the proximal residual gland would have adequate endocrine and exocrine function if the distal gland is resected in an extended distal pancreatectomy, an option is to preserve the uninjured portion of the distal gland. This is done by dividing the pancreas at the site of the injury and performing a Roux-en-Y pancreaticojejunostomy to allow the distal pancreas to drain into the jejunal limb.

colleagues' study, 37 patients with proximal pancreatic injury were managed by closed-suction drainage alone, resulting in a modest 13.5% fistula and abscess rate. Pancreatography was not performed in these patients, so the status of the pancreatic duct was not defined, and it remains unclear whether this technique is truly effective in the presence of a major

pancreatic duct injury. In the Duchesne and colleagues report, 35 patients had AAST grade I or II pancreatic injuries by CT scan and were intentionally managed nonoperatively. Five (14.3%) failed nonoperative management because of missed bowel injury ($n = 2$) and pancreatic abscess ($n = 3$), all classified as AAST grade II injuries. These failures of

nonoperative management survived but had a significantly longer length of stay (19 days versus 9 days). Operative exploration and drainage of even low-grade pancreatic injuries remain a prudent approach.

Both of these reports emphasize the importance of determining the status of the pancreatic duct. If the duct and its branches are not injured, nonoperative management is likely to be successful, and the role for detailed description of pancreatic duct anatomy advocated by Takishima and colleagues is relevant.⁸⁵ If no effort is made at determining the status of the pancreatic duct, at least wide drainage is mandatory. This approach is likely to be successful most of the time since injury to the main pancreatic duct is unusual; when it fails, however, the consequences are significant and morbid.^{4,6}

If the main pancreatic duct is injured or transected, distal resection is preferred, with the option of Roux-en-Y drainage of a long or significant distal pancreas that the surgeon is loath to sacrifice. Damage control drainage remains a viable lifesaving first operation. Finally, postoperative ERCP and transductal injury stenting appear to be another viable option, particularly in children, and particularly with very experienced endoscopists.^{1,53}

In the case of an incomplete pancreatic parenchymal transection, some surgeons have described an end jejunum-to-side pancreas anastomosis. This technique is not recommended because of the difficulty in ensuring the integrity of the anastomosis and potential for a high-output pancreatic fistula from the posterior pancreatic wound. Stone and colleagues from Emory University illustrated the high complication rate associated with this dated technique. Of 7 patients in whom the technique was used (among 283 patients), 5 (71%) developed a fistula and 3 (43%) died.⁶⁸

Insertion of a needle catheter jejunostomy or small feeding tube jejunostomy at the time of initial celiotomy should be considered for all patients with grade III to V pancreatic injuries. This allows early postoperative enteral nutrition, rather than committing the patient who cannot tolerate oral or gastric feedings to total parenteral nutrition.⁸⁶ There is some morbidity related to surgically placed feeding tubes. Our experience is that feeding jejunostomies have a major complication rate of 4% in severely injured patients.⁸⁷ Needle catheter jejunostomies were associated with fewer complications than the larger, Witzel tube jejunostomy—hence, our preference for this smaller-caliber feeding tube and elemental or short-chain polypeptide feeding formulas, which we prefer.^{73,87}

Combined Pancreatic-Duodenal Injuries

Fortunately, severe combined pancreatic head and duodenal injuries are rare. Forty-eight of 1,404 patients (3%) with pancreatic injuries reported between 1981 and 1990 underwent pancreatoduodenectomy.⁸⁸ These injuries are most commonly caused by penetrating wounds and occur in association with multiple other intra-abdominal injuries. In fact, these associated injuries are the primary cause of mortality and emphasize again the priorities of hemorrhage control and contamination control in dealing with pancreatic or duodenal injury. The major immediate mortality in patients with combined pancreatic and duodenal injuries is attributable to major vascular injury in the vicinity of the head of the

pancreas. If immediate control of hemorrhage and resuscitation can be obtained, the Whipple resection remains the preferred option in that select group of patients with unreconstructable injury to the ampulla or proximal pancreatic duct or with combined massive destruction of the duodenal and pancreatic head. Essentially, in these patients, pancreatoduodenectomy is the completion of surgical débridement of devitalized tissue. For patients with hemodynamic instability, hypothermia, coagulopathy, and acidosis, a staged operative approach (damage control surgery) is advocated, first obtaining control of hemorrhage, then managing bowel and bacterial contamination, and, lastly, identifying the anatomy of the injury, followed by resuscitation in the intensive care unit. The patient is returned to the operating room for definitive reconstruction and anastomoses when stabilized, generally 24 to 48 hours later.

Because of the large number of possible combinations of injuries to the pancreas and duodenum, no one form of therapy is appropriate for all patients. In Feliciano and colleagues' review of 129 cases of combined pancreatic-duodenal injuries, 24% of the patients were treated with simple repair and drainage, 50% underwent repair and pyloric exclusion, and only 10% required a Whipple procedure.⁸² The best treatment option is predicated on the integrity of the distal common bile duct and ampulla, as well as the severity of the duodenal injury [see Figure 5]. For that reason, every patient with a combined pancreatic-duodenal injury requires a cholangiogram, a pancreatogram, and evaluation of the ampulla. When the common bile duct and ampulla are intact (as is the situation in the majority of the cases), the duodenum can be closed primarily and the pancreatic injury treated as previously described. If the status of the pancreatic duct cannot be made intraoperatively, wide external drainage of the pancreatic head with closed suction drains should be performed rather than a total pancreatectomy and early postoperative ERCP or MRCP performed.

It may be advisable to divert gastric contents away from the duodenal repair in the presence of severe injury to the duodenum. Duodenal "diverticulization" employs primary closure of the duodenal wound, antrectomy, vagotomy, end-to-side gastrojejunostomy, T-tube common bile duct drainage, and lateral tube duodenostomy. The concept is to completely divert both gastric and biliary contents away from the duodenal injury, provide enteral nutrition via the gastrojejunostomy, and convert a potential uncontrolled lateral duodenal fistula to a controlled fistula [see Figure 6]. A less formidable and less destructive alternative is the "pyloric exclusion," which does not employ antrectomy, biliary diversion, or vagotomy [see Figure 7].^{72,89-91} This procedure is performed through a gastrotomy and consists of grasping the pylorus with a Babcock clamp and suturing closed the pylorus with an absorbable size 0 polyglycolic acid or Maxon suture and constructing a loop gastrojejunostomy. This diverts gastric flow away from the duodenum for several weeks while the duodenal and pancreatic injuries heal. The pylorus eventually opens (2 weeks to 2 months), and the gastrojejunostomy functionally closes. Fang and colleagues at Chang-Gung Memorial Hospital in Taiwan described a technical method of controlled release of the pyloric exclusion knot, thereby timing the opening of the pyloric

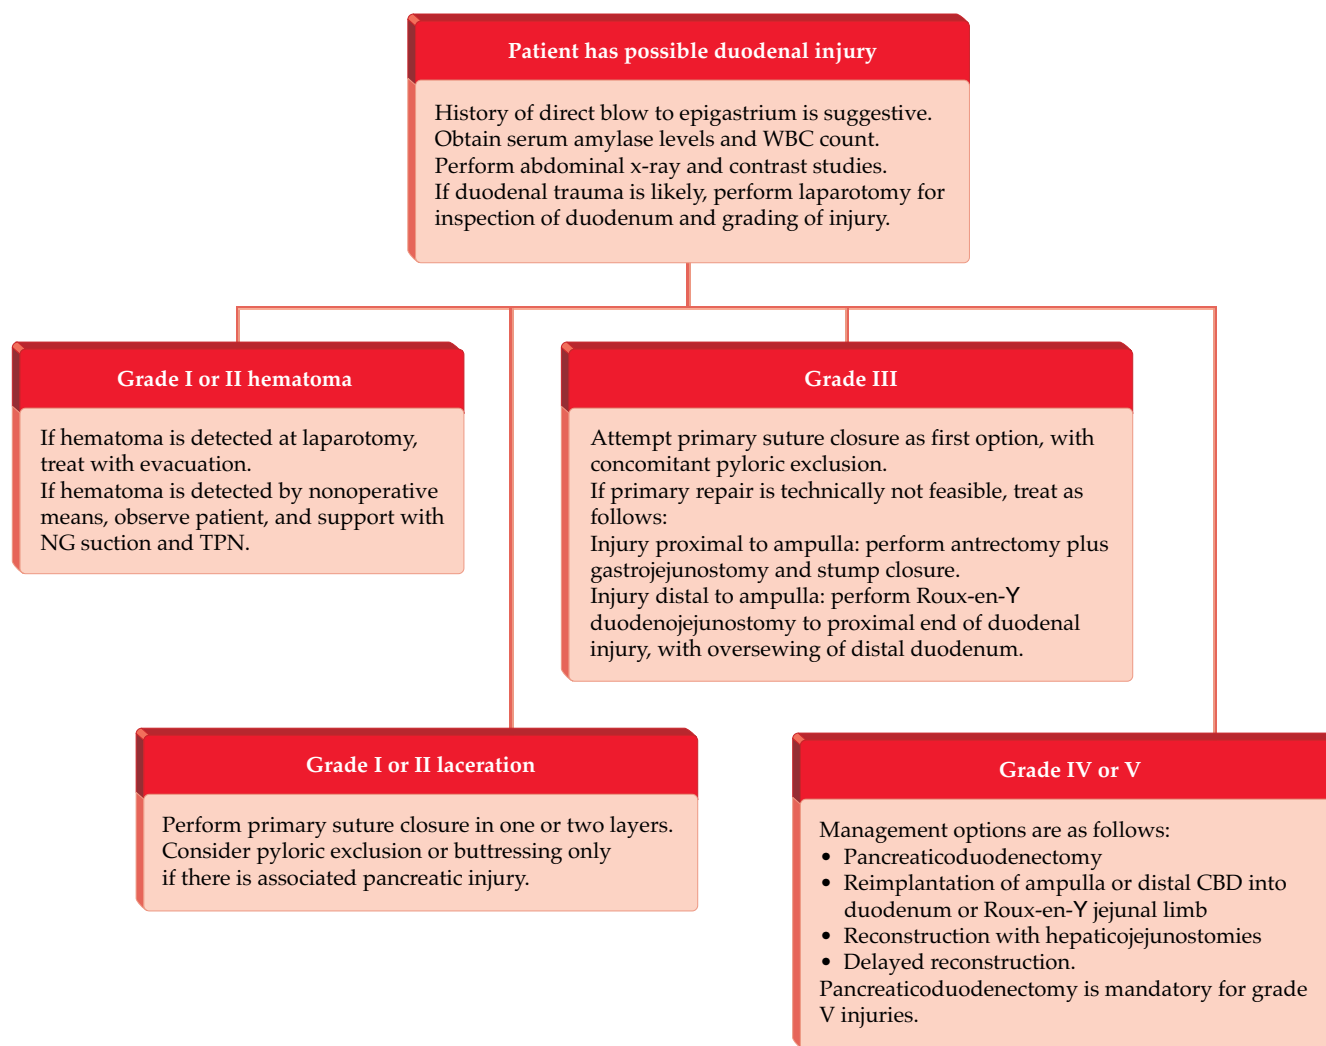

Figure 5. Treatment of duodenal injury. Algorithm outlining the treatment of duodenal injury. CBD = common bile duct; NG = nasogastric; TPN = total parenteral nutrition; WBC = white blood cell count.

occlusion.⁹² Marginal ulceration at the site of gastrojejunostomy has been reported from 5 to 33% of patients in whom a vagotomy was not performed.⁹⁰⁻⁹³ Pyloric exclusion is generally reserved for severe combined duodenal and pancreatic head and duodenal injuries in which a Whipple procedure is not required. Few advocate pyloric exclusion for isolated pancreatic injuries.

In very massive injuries of the proximal duodenum and head of the pancreas, destruction of the ampulla and proximal pancreatic duct or distal common bile duct may preclude reconstruction. In addition, because the head of the pancreas and the duodenum have a common arterial supply, it is essentially impossible to entirely resect one without making the other ischemic. In this situation, a pancreatoduodenectomy is required. Between 1961 and 1994, 184 Whipple procedures were reported for trauma, with 26 operative deaths (14%) and 39 delayed deaths, for a 64% overall survival rate.⁸⁸ However, more recent experience suggests that with appropriate selection criteria, pancreatoduodenectomy for injury can be performed with morbidity and mortality similar to those described for resections done for cancer.⁹⁴⁻⁹⁶

Nonoperative Management in Children

Major pancreatic duct injury in children is rare, with an incidence of 0.12% of children with blunt abdominal trauma.⁵² Most pediatric pancreatic injuries are grade I or II injuries, without major pancreatic duct injury. As a result, several authors have advocated managing all blunt pediatric pancreatic injuries nonoperatively, with bowel rest, serial abdominal CT to observe for pseudocyst formation, and subsequent percutaneous drainage as required.^{7,97-99} However, the high morbidity and prolonged hospital course of these patients may not be justified given the good recovery from distal pancreatectomy with splenic salvage.¹⁰ Pseudocysts develop in 40 to 100% of children with major ductal injury,^{7,8,100} and recurrent episodes of pancreatitis can occur remote to the time of injury.^{36,101} ERCP with proximal stenting of ductal injuries is an additional adjunct to care in these patients but requires the availability of a skilled pediatric endoscopist. A report from Toronto details the management of 35 children with pancreatic trauma over a 10-year time period.⁷ Twenty-three had early diagnosis (< 24 hours), whereas in 12, the diagnosis was initially missed. Twenty-eight were managed

Figure 6. Duodenal diverticularization. Duodenal diverticularization consists of antrectomy with gastrojejunostomy, tube duodenostomy, vagotomy, and peripancreatic drainage.

nonoperatively. A subsequent report examined in more detail 10 of these patients having a pancreatic duct transection.⁹⁹ Forty-four percent developed pseudocyst, and all were managed with percutaneous drainage; 75% had atrophy of the distal pancreatic remnant, but there was no evidence of endocrine or exocrine dysfunction. A report from Japan demonstrated 100% pseudocyst development in five children with pancreatic duct injury managed nonoperatively.⁸ The data seem to suggest that pediatric pancreatic injuries can be successfully managed nonoperatively, but with a high incidence of pseudocyst formation requiring further hospitalization and interventions and with atrophy of the distal remnant. Other pediatric surgical authors point out the benefits of distal pancreatectomy in terms of shortening hospital stay and interventions.^{10,52,102}

Complications

The incidence of complications following pancreatic injury remains uncomfortably high. Between 20 and 40% of patients who undergo surgical intervention of a pancreatic injury have a complicated postoperative course and even higher if a combined pancreatoduodenal wound has occurred [see Table 2].⁵

Although the majority of complications related to pancreatic injury are self-limiting or treatable, sepsis and multisystem organ failure are responsible for nearly 30% of the deaths in pancreatic trauma. In some series, up to one half of the postoperative complications could have been avoided with careful inspection of the pancreas and accurate determination of the status of the main pancreatic duct.²⁸

FISTULA

Postoperative pancreatic fistula has been defined as any measurable drain output with an amylase greater than three times serum.⁷¹ This is the most common complication following pancreatic injury, with an incidence of 7 to 20%, rising to 26 to 35% after combined pancreatoduodenal injury.^{34,61,103,104} Direct suture closure of the main pancreatic duct may help minimize this complication, but fibrin sealants do not seem to provide any advantage.¹⁰⁵ The vast majority of these are minor (less than 200 cc/day) and spontaneously resolve within 2 weeks of injury, providing that adequate external drainage has been provided. In a multicenter review of distal pancreatectomy for trauma, the postoperative fistula rate was 14% (10 of 71), with spontaneous fistula closure in 89% (8 of 9) of survivors in 6 to 54 days.⁸³ One patient required

Figure 7. Pyloric exclusion. Pyloric exclusion consists of closure of the pylorus from within the stomach, followed by gastrojejunostomy. The procedure eliminates discharge of gastric acid into the duodenum, thus minimizing the stimulation of pancreatic secretion and reducing morbidity if there is breakdown of a repair.

extirpation of a residual pancreatic sequestrum to facilitate fistula closure. This compares with a 3.3% fistula rate in elective distal pancreatectomy for chronic pancreatitis.⁷⁶ High-output fistulae (greater than 700 cc/day) are rare and generally require longer periods of external drainage or surgical intervention for resolution. If a high-output fistula fails to progressively decrease in volume or persists more than

10 days, ERCP is indicated and can be most helpful in establishing the cause of the persistent fistula and planning further therapy. Nutritional support must be provided throughout this period. The surgeon's foresight in placing a feeding jejunostomy at the time of initial trauma laparotomy is now rewarded. Low-fat, higher pH elemental feeding formulas cause less pancreatic stimulation than standard enteral formulas and should be tried prior to committing the patient to total parenteral nutrition.⁷³ A somatostatin analogue (octreotide acetate [Sandostatin]) has shown promise in treating prolonged, high-output pancreatic fistulae, but only after eradicating any infection and in the absence of pancreatic duct obstruction or stricture.¹⁰⁶

Octreotide as an adjuvant to standard fistula management probably diminishes fistula output, but its shortening of the time to fistula closure remains to be proven.¹⁰⁷ Somatostatin analogues do seem to prevent postoperative complications and fistula formation in patients undergoing elective pancreatic resection, although nonrandomized reports on the efficacy of somatostatin analogues in pancreatic trauma patients are contradictory.^{108,109} In addition, the trials demonstrating a decrease in postoperative complications with octreotide use in elective pancreatic resection initiated octreotide in the preoperative period, a time frame not applicable to the trauma setting.¹⁰⁹ Treatment typically begins with 50 µg subcutaneously every 12 hours but can increase to 1,000 µg/day. Octreotide has been included in total parenteral nutrition solutions, although this remains controversial and is not recommended by the 1997 package insert because of the formation of glycosyl octreotide conjugates that may decrease efficacy.¹¹⁰ Major side effects are unpredictable changes in serum glucose, pain at the injection site, and a variety of nonspecific gastrointestinal complaints.

ABSCESSSES

The incidence of abscess formation after pancreatic trauma ranges from 10 to 25%, depending on the number and type of associated injuries. Early operative or percutaneous decompression or evacuation is critical, although the mortality rate in this group of patients remains about 25%.^{82,111} The intra-abdominal abscess is most often subfascial or peripancreatic; a true pancreatic abscess is unusual, resulting from inadequate débridement of dead tissue or inadequate initial drainage.^{61,84,104,112} True pancreatic abscesses are often not amenable or responsive to percutaneous drainage, and prompt surgical débridement and drainage are required. Percutaneous decompression may be helpful in distinguishing between abscess and pseudocyst.

Table 2 Factors Determining Severity of Duodenal Injury

Factor	Degree of Injury	
	Mild	Severe
Means of injury	Stab	Blunt force or missile
Size of injury	≤ 75% of circumference	> 75% of circumference
Location of injury in duodenum	D3, D4	D1, D2
Interval between injury and repair	≤ 24 hr	> 24 hr
Adjacent injury to CBD	Absent	Present

CBD = common bile duct.

PANCREATITIS

Transient abdominal pain and a rise in the serum amylase concentration may be anticipated in 8 to 18% of postoperative patients.^{23,84,113} This type of pancreatitis is treated with nasogastric decompression, bowel rest, and nutritional support and can be expected to resolve spontaneously. A much more infrequent but deadly complication is hemorrhagic pancreatitis. The first sign of this complication may be bloody pancreatic drainage or a fall in the serum hemoglobin concentration, with the patient rapidly becoming desperately ill. It is fortunate that this complication occurs in less than 2% of operative pancreatic trauma patients since mortality may approach 80% with no effective treatment.^{61,75}

SECONDARY HEMORRHAGE

Postoperative hemorrhage requiring blood transfusion may occur in 5 to 10% of pancreatic trauma patients, particularly when inadequate external drainage has been afforded after pancreatic débridement or when intra-abdominal infection has developed.^{113,114} These patients generally require reoperation for control, although angiographic embolization may be an effective alternative.

PSEUDOCYSTS

Missed blunt pancreatic injuries, or those intentionally managed nonoperatively, often result in the formation of a pseudocyst. One report tabulated 22 pseudocysts in 42 blunt pancreatic trauma patients managed nonoperatively.²⁷ The status of the pancreatic duct is the key determinant to

treatment of a pancreatic pseudocyst. If the pancreatic duct is intact, percutaneous drainage of the pseudocyst is likely to be effective. If the pseudocyst is secondary to a major pancreatic ductal disruption, percutaneous drainage will not provide definitive therapy but will convert a pseudocyst to a chronic fistula. ERCP should therefore precede any percutaneous drainage. If pancreatic duct stenosis or injury is demonstrated, treatment options include (1) reexploration and partial gland resection, (2) distal gland internal Roux-en-Y drainage, and (3) endoscopic transpapillary stenting of the pancreatic duct.⁴⁹ The experience of Kouchi and colleagues of Japan suggests that a pseudocyst greater than 10 cm in size will require surgical decompression.⁸

EXOCRINE AND ENDOCRINE INSUFFICIENCY

Both exocrine and endocrine insufficiency are unusual after pancreatic trauma. Animal and human studies suggest that a residuum of 10 to 20% of normal pancreatic tissue is adequate for pancreatic function,^{24,115} implying that any resection distal to the mesenteric vessels should leave adequate functioning pancreatic tissue. The multicenter study of 74 cases of distal pancreatic resection described earlier documented only 1 case of endocrine deficiency (diet-controlled hyperglycemia following 80% pancreatectomy) and no instance of exocrine insufficiency.⁸⁴ Balasegaram reported no pancreatic insufficiency after resections of up to 90% of the pancreas.¹⁰³ In contrast, patients with chronic pancreatitis who undergo distal pancreatectomy have an incidence of diabetes ranging from 15% (0 to 33% gland resected) to 64% (50 to 75% gland resected).⁷⁶

10 INJURIES TO THE GREAT VESSELS OF THE ABDOMEN

David V. Feliciano, MD, FACS

In patients who have injuries to the great vessels of the abdomen, the findings on physical examination generally depend on whether a contained hematoma or active hemorrhage is present.¹ In the case of contained hematomas around the vascular injury in the retroperitoneum, the base of the mesentery, or the hepatoduodenal ligament, the patient often has only modest hypotension in transit or on arrival at the emergency center. The hypotension can be temporarily reversed by the infusion of fluids and may not recur until the hematoma is opened at the time of laparotomy. This is usually the situation when an abdominal venous injury is present. In the case of active intraperitoneal hemorrhage, the patient typically has significant hypotension and may have a distended abdomen on arrival. Another physical finding that is occasionally noted in association with an injury to the common or external iliac artery is intermittent or complete loss of a pulse in the ipsilateral femoral artery; this finding in a patient with a transpelvic gunshot wound is pathognomonic of an injury to the iliac artery.

Injuries to the great vessels of the abdomen are caused by penetrating wounds in 90 to 95% of cases; accordingly, they are often accompanied by injuries to multiple intra-abdominal organs, including those in the gastrointestinal (GI) tract.²⁻⁵ The general principles governing the sequencing of repairs of injuries to the great vessels and the GI tract are outlined elsewhere.

A hematoma [see *Figure 1* and *Figure 2*] or hemorrhage associated with an injury to a great vessel of the abdomen occurs in one of the three zones of the retroperitoneum or in the portal-retrohepatic area of the right upper quadrant. The magnitude of injury is usually described according to the Abdominal Vascular Organ Injury Scale, devised in 1992 by the American Association for the Surgery of Trauma [see *Table 1*].⁶

Injuries in Zone 1

SUPRAMESOCOLIC

It is helpful to divide midline retroperitoneal hematomas into those that are supramesocolic and those that are inframesocolic.¹ Hematoma or hemorrhage in the midline supramesocolic area of zone 1 is cause to suspect the presence of an injury to the suprarenal aorta, the celiac axis, the proximal superior mesenteric artery, or the proximal renal artery.

When a hematoma is present in the midline supramesocolic area, one usually has time to perform left medial visceral rotation [see *Figure 3*].^{7,8} The advantage of this technique is that it allows visualization of the entire abdominal aorta, from the aortic hiatus of the diaphragm to the common iliac arteries [see *Figure 4*].

Obvious disadvantages include the 5 to 7 minutes required to complete the maneuver when the surgeon is inexperienced; the risk of damage to the spleen, the left kidney, or the posterior left renal artery as the maneuver is performed; and the anatomic distortion that results when the left kidney and the left renal artery are rotated anteriorly. When the hematoma is near the aortic hiatus of the diaphragm, it may be advisable to leave the left kidney in its fossa, thereby eliminating potential damage to the structure as well as the distortion resulting from rotation. Because of the density of the celiac ganglia and nerve plexus and the lymphatic vessels surrounding the upper abdominal aorta, this portion of the aorta is difficult to visualize even when left medial visceral rotation has been performed. It is frequently helpful to transect the left crus of the aortic hiatus in the diaphragm at the 2 o'clock position to allow exposure of the distal descending thoracic aorta above the hiatus. Visualization of this portion of the vessel is much easier to achieve than visualization of the diaphragmatic or visceral abdominal aorta below, and an aortic cross-clamp can be applied much more quickly at this level.

Active hemorrhage from the midline supramesocolic area is controlled temporarily by packing with laparotomy pads or using an aortic compression device [see *Figure 5*].^{9,10} A definitive approach is to divide the lesser omentum manually, retract the stomach and esophagus to the left, and manually dissect in the area just below the aortic hiatus of the diaphragm to obtain rapid exposure of the supraceliac abdominal aorta.¹¹ An aortic cross-clamp can then be applied. Distal control of the upper abdominal aorta is difficult to obtain because of the presence of the anteriorly located celiac axis and superior mesenteric artery. In young trauma patients who are otherwise healthy, ligation and division of the celiac axis allow easier application of the distal aortic clamp and better exposure of the supraceliac area for subsequent vascular repair.¹²

Small penetrating wounds to the supraceliac abdominal aorta are repaired with a continuous 3-0 or 4-0 polypropylene suture. If two small perforations are adjacent to each other, they can be connected and the defect closed in a transverse fashion. If closure of a perforation would result in significant narrowing of the aorta or if a portion of the aortic wall is missing, patch aortoplasty with polytetrafluoroethylene (PTFE) is indicated. On rare occasions, in patients with extensive injuries to the diaphragmatic or supraceliac aorta, resection of the area of injury and insertion of a vascular conduit are indicated. Even though many of these patients have associated gastric, enteric, or colonic injuries, the most appropriate prosthesis with such a life-threatening injury is a 12, 14, or 16 mm woven Dacron, albumin-coated Dacron, or PTFE graft [see *Figure 6*].¹³ Provided that vigorous intraoperative irrigation is performed after repair of GI tract perforations, that proper graft coverage is ensured, and that

Figure 1 Algorithm illustrating management of intra-abdominal hematoma found at operation after penetrating trauma.

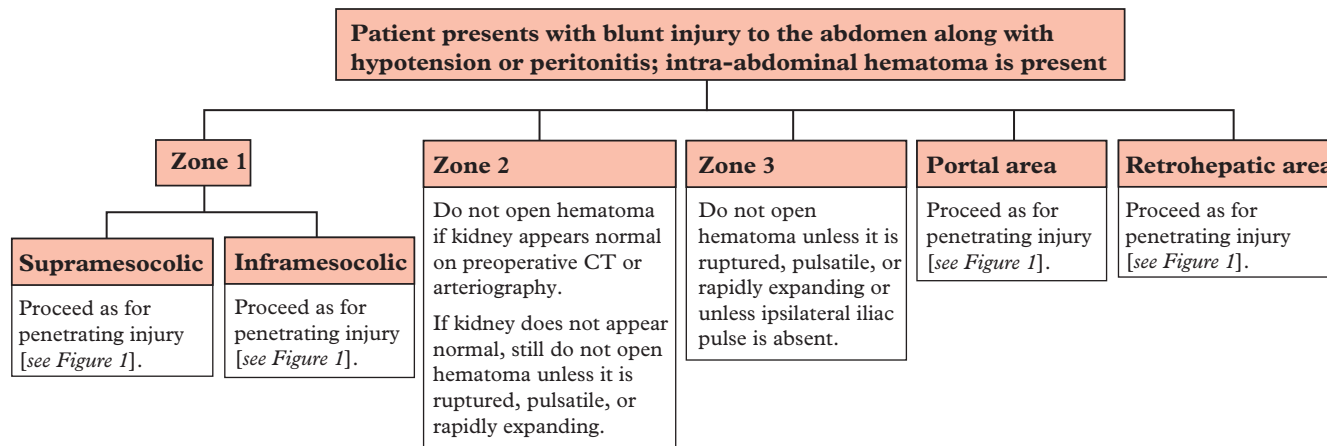

Figure 2 Algorithm illustrating management of intra-abdominal hematoma found at operation after blunt trauma.
CT = computed tomography.

perioperative antibiotics are appropriately employed, it is extraordinarily rare for a prosthesis inserted in the healthy aorta of a young trauma patient to become infected.

The aortic prosthesis is sewn in place with a continuous 3-0 or 4-0 polypropylene suture. Both ends of the aorta are flushed before the distal anastomosis is completed, and the distal aortic cross-clamp is removed before the final knot is tied to eliminate air from the system. The proximal aortic cross-clamp is removed very slowly as the anesthesiologist rapidly infuses fluids and intravenous bicarbonate to reverse so-called washout acidosis from the previously ischemic lower extremities. The retroperitoneum is then irrigated with an antibiotic solution and closed over the graft in a watertight fashion with an absorbable suture.

Cross-clamping of the diaphragmatic or supraceliac abdominal aorta in a patient with hemorrhagic shock results in severe ischemia of the lower extremities. Restoration of flow through

the repaired abdominal aorta may then cause a reperfusion injury in addition to the ischemic edema that develops in the muscle compartments below the knee. In a patient who is hemodynamically stable after repair of the suprarenal abdominal aorta and other injuries, measurement of compartmental pressures below the knees should be performed before the patient is moved from the operating room (OR). Pressures in the range of 30 to 35 mm Hg are likely to rise in the intensive care unit; accordingly, at many centers, bilateral below-the-knee two-incision four-compartment fasciotomies would be performed in this situation.¹⁴

The survival rate in patients with injuries to the suprarenal abdominal aorta had been 30 to 35% but was lower than 10% in one 2001 review.^{4,13}

Injuries to branches of the celiac axis are often difficult to repair because of the amount of dissection required to remove the dense neural and lymphatic tissue in this area. Because

Table 1 AAST Abdominal Vascular Organ Injury Scale

Grade	Characteristics of Injury	OIS Grade	ICD-9	AIS-90
I	Unnamed superior mesenteric artery or superior mesenteric vein branches	I	902.20/902.39	NS
	Unnamed inferior mesenteric artery or inferior mesenteric vein branches	I	902.27/902.32	NS
	Phrenic artery or vein	I	902.89	NS

	Vena cava, retrohepatic or suprahepatic	V	902.19	5
	Aorta, suprarenal and subdiaphragmatic	V	902.00	4

AAST = American Association for the Surgery of Trauma; AIS = Abbreviated Injury Scale; ICD = International Classification of Diseases; NS = not specified; OIS = Organ Injury Scale.

This classification is applicable to extraparenchymal vascular injuries. If the vessel injury is within 2 cm of the parenchyma of a specific organ, one should refer to the injury scale for that organ.

*Increase grade by I if there are multiple injuries involving more than 50% of vessel circumference.

†Reduce grade by I if laceration is less than 25% of vessel circumference.

Figure 3 Left medial visceral rotation is performed by means of sharp and blunt dissection with elevation of the left colon, the left kidney, the spleen, the tail of the pancreas, and the gastric fundus.

most patients have excellent collateral flow in the upper abdomen, major injuries to either the left gastric or the proximal splenic artery generally should be ligated. Because the common hepatic artery may have a larger diameter than either of these two arteries, an injury to this vessel can occasionally be repaired by means of lateral arteriorrhaphy, an end-to-end anastomosis, or the insertion of a saphenous vein graft. One should not worry about ligating the hepatic artery proper proximal to the origin of the gastroduodenal artery as there is extensive collateral flow to the liver from the midgut. When the entire celiac axis is injured, it is best to ligate all three vessels and forgo any attempt at repair. In one recent review of 13 patients with injuries to the celiac axis, the overall survival was 38%.¹⁵

Injuries to the superior mesenteric artery are managed according to the anatomic level of the perforation or thrombosis.¹⁶ On rare occasions, in patients with injuries beneath the neck of the pancreas, one may have to transect the pancreas to obtain proximal control. Another option is to perform left medial visceral rotation (see above) and apply a clamp directly to the origin of the superior mesenteric artery. Injuries to the superior mesenteric artery in this area or just beyond the base of the mesocolon are often associated with injuries to the pancreas.

Figure 4 Shown is an autopsy view of the supraceliac aorta and the celiac axis, the proximal superior mesenteric artery, and the medially rotated left renal artery after removal of lymphatic and nerve tissue. Reproduced with permission from Feliciano DV. Abdominal vascular injury. In: Moore EE, Feliciano DV, Mattox KL, editors. Trauma. 5th ed. New York: McGraw-Hill; 2004.

The potential for a postoperative leak from the injured pancreas near the arterial repair has led numerous authors to suggest that any extensive injury to the artery at this location should be ligated [see Figure 7].

Because of the intense vasoconstriction of the distal superior mesenteric artery in patients who have sustained exsanguinating hemorrhage from more proximal injuries treated with ligation, the collateral flow from the foregut and hindgut is often inadequate to maintain the viability of the organs in the distal midgut, especially the cecum and the ascending colon. Therefore, it is safest to place a saphenous vein or PTFE graft on the distal infrarenal aorta, away from the pancreatic injury and any other upper abdominal injuries.¹⁷ Such a graft can be tailored to reach the side or the anterior aspect of the superior mesenteric artery, or it can be attached to the transected distal superior mesenteric artery in an end-to-end fashion without significant tension [see Figure 8]. Soft tissue must be approximated over the aortic suture line of the graft to prevent the development of an aortoenteric fistula in the postoperative period.

In patients with severe shock from exsanguination caused by a complex injury to the superior mesenteric artery, damage-control laparotomy is indicated [see Damage-Control Laparotomy, below]: the injured area should be resected and a temporary intraluminal Argyle, Javid, or Pruitt-Inahara shunt inserted to maintain flow to the midgut during resuscitation in the surgical intensive care unit (SICU).¹⁸ When ligation is indicated for more distal injuries to the superior mesenteric

Figure 5 An aortic compression device is used to control hemorrhage from the visceral portion of the abdominal aorta.

Figure 6 A 22-year-old man with a gunshot wound to the right upper quadrant had injuries to the prepyloric area of the stomach and to the supraceliac abdominal aorta. The aortic injury was managed by means of segmental resection and replacement with a 16 mm polytetrafluoroethylene graft. The patient went home 46 days after injury. Reproduced with permission from Feliciano DV. Abdominal vascular injury. In: Moore EE, Feliciano DV, Mattox KL, editors. Trauma. 5th ed. New York: McGraw-Hill; 2004.

Figure 7 An 18-year-old man experienced a gunshot wound to the head of the pancreas and the proximal superior mesenteric artery. A Whipple procedure was performed, and a 6 mm polytetrafluoroethylene graft was placed in the artery. The artery-graft suture line dehiscenced secondary to a pancreatic leak on day 30 after injury, and the patient died on day 42.

artery, segments of the ileum or even the right colon may have to be resected because of ischemia.

The survival rate in patients with penetrating injuries to the superior mesenteric artery is approximately 55 to 60% overall [see Table 2] but only 20 to 25% when any form of repair more complex than lateral arteriorrhaphy is necessary.^{1-4,17,19}

An injury to the proximal renal artery may also be present under a supramesocolic hematoma or bleeding area. When active hemorrhage is present, control of the supraceliac abdominal aorta in or just below the aortic hiatus must be obtained. When only a hematoma or a known thrombosis of the proximal renal artery is present, proximal vascular control can be obtained by elevating the transverse mesocolon and dissecting the vessel from the lateral aspect of the abdominal aorta. Options for repair of either the proximal or the distal renal artery are described elsewhere [see Injuries in Zone 2, below].

The superior mesenteric vein is the other great vessel of the abdomen that may be injured in the supramesocolic or retro-mesocolic area of the midline retroperitoneum. Because of the overlying pancreas, the proximity of the uncinate process, and the close association of this vessel with the superior mesenteric artery, repair of the superior mesenteric vein is quite difficult. As with injuries to the superior mesenteric artery (see above), one may have to transect the neck of the pancreas between non-crushing vascular or intestinal clamps to gain access to a perforation of the superior mesenteric vein. An injury to this vein below the inferior border of the pancreas can be managed by compressing it manually between one's fingers as an assistant places a continuous 5-0 polypropylene suture to complete the repair. When a penetrating injury to the vein has a posterior component, one must ligate multiple collateral vessels entering the vein in this area to achieve proper visualization.

There is excellent evidence that young trauma patients tolerate ligation of the superior mesenteric vein well when vigorous postoperative fluid resuscitation is performed to reverse the peripheral hypovolemia that results from splanchnic hypervolemia.^{20,21} Typically, ligation is followed almost immediately by swelling of the midgut and discoloration suggestive of impending ischemia. In such cases, temporary coverage of the midgut with a silo, followed by early reoperation, may be necessary to reassure the operating surgeon that the ischemia has not become permanent.

The survival rate in patients with injuries to the superior mesenteric vein ranges from 36 to 71%, depending on whether other vascular injuries are present [see Table 3].^{1-4,20} In three reviews in 2001, the survival rate was 58%.²⁻⁴

INFRAMESOCOLIC

The lower area of the midline retroperitoneum in zone 1 is known as the midline inframesocolic area. Injuries to either the infrarenal abdominal aorta or the inferior vena cava occur in this area.

An injury to the inframesocolic abdominal aorta that is under a hematoma is controlled by performing the same maneuvers used to gain proximal control of an infrarenal abdominal aortic aneurysm. The infrarenal abdominal aorta is exposed by pulling the transverse mesocolon up toward the patient's head, eviscerating the small bowel to the right side of the abdomen, and opening the midline retroperitoneum until the left renal vein is exposed. A proximal aortic cross-clamp is then placed immediately inferior to this vessel [see Figure 9]. When the entire inframesocolic area is distorted by the presence of a large pulsatile hematoma, the inexperienced trauma surgeon should remember that the hole in the infrarenal abdominal aorta is under the highest point of the hematoma (the so-called Mt. Everest phenomenon). When there is active hemorrhage from this area, rapid proximal control is obtained in the same fashion or, if necessary because of the need to apply compression, by dividing the lesser omentum and applying the cross-clamp just below the aortic hiatus of the diaphragm. Distal control of the infrarenal abdominal aorta is obtained by dividing the midline retroperitoneum down to the aortic bifurcation, taking care to avoid the origin of the inferior mesenteric artery on the left side.

Injuries to the infrarenal aorta are repaired by means of lateral aortorrhaphy, patch aortoplasty, an end-to-end anastomosis, or insertion of a Dacron or PTFE graft. Much as with injuries to the suprarenal abdominal aorta in young trauma patients, it is rarely possible to place a tube graft larger than 12, 14, or 16 mm. Because the retroperitoneal tissue is often thin at this location in young patients, an important adjunctive measure after the aortic repair is to mobilize the gastrocolic omentum, flip it into the lesser sac superiorly, and then bring it down over the infrarenal aortic graft through a hole in the left transverse mesocolon. An alternative is to mobilize the gastrocolic omentum away from the right side of the colon and then swing the mobilized tissue into the area just below the ligament of Treitz to cover the graft. With either technique, it is mandatory to suture the viable omental pedicle superior to the aortic suture line to prevent a postoperative aortoduodenal fistula.^{22,23}

The survival rate in patients with injuries to the infrarenal abdominal aorta had been approximately 45% in series published from 1974 to 1992 but was 34% in a 2001 review [see Table 2].¹⁻⁴

Figure 8 (a) When complex grafting procedures to the superior mesenteric artery are necessary, it may be dangerous to place the proximal suture line near an associated pancreatic injury. (b) The proximal suture line should be on the lower aorta, away from the upper abdominal injuries, and should be covered with retroperitoneal tissue.

Injury to the inferior vena cava below the liver should be suspected when the aorta is found to be intact underneath an inframesocolic hematoma, when such a retroperitoneal hematoma appears to be more extensive on the right side of the abdomen than on the left, or when there is active hemorrhage coming through the base of the mesentery of the ascending colon or the hepatic flexure. It is certainly possible to visualize

the inferior vena cava through the midline retroperitoneal exposure just described (see above); however, most surgeons are more comfortable with visualizing the vessel by mobilizing the right half of the colon and the C loop of the duodenum.¹ With this right medial visceral rotation maneuver, the right kidney is left in situ unless there is an associated injury to the posterior aspect of the right renal vein, to the suprarenal vena cava, or to

Table 2 Survival after Injuries to Arteries in the Abdomen

Injured Artery	Asensio et al ² (2000)		Davis et al ³ (2001)*	Tyburski et al ⁴ (2001)

[†]Excludes retrohepatic vena cava.

the right kidney itself. Right medial visceral rotation, in conjunction with the Kocher maneuver, permits visualization of the entire vena caval system from the confluence of the iliac veins to the suprarenal vena cava below the liver. Local exposure of the iliac vein–vena cava junction in the lower abdomen and of the renal vein–vena cava junction in the upper abdomen is appropriate before completion of right medial visceral rotation. This measure allows rapid application of proximal and distal vascular clamps on the inferior vena cava in the event that exsanguinating hemorrhage results when the caval injury is exposed.

For proper exposure of a hole in a large vein such as the inferior vena cava, the loose retroperitoneal fatty tissue

must be dissected away from the wall of the vessel. Active hemorrhage coming from the anterior surface of the inferior vena cava is best controlled by applying a Satinsky vascular clamp. If it is difficult to apply this clamp, one should try grasping the area of the perforation with a pair of vascular forceps or several Judd-Allis clamps; this step may facilitate safe application of the Satinsky clamp.²⁴ When the perforation in the inferior vena cava is more lateral or posterior, it is often helpful to compress the vessel proximally and distally around the perforation, using gauze sponges placed in straight sponge sticks. On occasion, an extensive injury to the inferior vena cava can be controlled only by completely occluding the entire inferior vena cava with large DeBakey aortic cross-clamps. This maneuver interrupts much of the venous return to the right side of the heart and is poorly tolerated by hypotensive patients unless the infrarenal abdominal aorta is cross-clamped simultaneously.

There are two anatomic areas in which vascular control of an injury to the inferior vena cava below the liver is difficult to obtain: (1) the confluence of the common iliac veins and (2) the junction of the renal veins with the inferior vena cava. One interesting approach to an injury to the inferior vena cava at the confluence of the iliac veins is temporary division of the overlying right common iliac artery, coupled with mobilization of the aortic bifurcation to the patient's left.²⁵ This approach yields a better view of the common iliac veins and the proximal inferior vena cava and makes repair considerably easier than it would be if the aortic bifurcation was left in place. Once the vein is repaired, the right common iliac artery is reconstituted via an end-to-end anastomosis. The usual approach to injuries to the inferior vena cava at its junction with the renal veins involves clamp or sponge-stick compression of the infrarenal and suprarenal vena cava, as well as control of both renal veins with Silastic loops to facilitate the direct application of angled vascular clamps. As noted, medial mobilization of the right kidney may permit the application of a partial occlusion clamp across the inferior vena cava at its junction with the right renal vein as an alternative approach to an injury in this area. Another useful technique for controlling hemorrhage from the inferior vena cava at any location is to insert a 5 or 30 mL Foley balloon catheter into the caval laceration and then inflate it in the lumen.^{26–28} Once the bleeding is controlled, vascular clamps are positioned around

Figure 9 Shown is a gunshot wound to the infrarenal abdominal aorta viewed through standard inframesocolic exposure. The patient's head is at the bottom of the photograph. Reproduced with permission from Feliciano DV, Burch JM, Graham JM, editors. *Abdominal vascular injury*. In: *Trauma*. 3rd ed. Stamford (CT): Appleton & Lange; 1996.

the perforation, and the balloon catheter is removed before repair of the vessel.

Anterior perforations of the inferior vena cava are managed by a transverse repair with a continuous 4-0 or 5-0 polypropylene suture. Much has been written about visualizing posterior perforations by extending anterior perforations, but in my experience, opportunities to apply this approach have been rare. It is often easier to roll the vena cava to one side to complete a continuous suture repair of a posterior perforation. When both anterior and posterior perforations have been repaired, there is usually a significant degree of narrowing of the inferior vena cava, which may lead to slow postoperative occlusion. If the patient's condition is unstable and a coagulopathy has developed, no further attempt should be made to revise the repair. If the patient is stable, there may be some justification for applying a large PTFE patch to prevent this postoperative occlusion [see Figure 10].

Ligation of the infrarenal inferior vena cava is appropriate for young patients who are exsanguinating and in whom a complex repair of the vessel would be necessary. After the damage-control abdominal procedure has been completed and a silo has been used to cover the midgut, it is, once again, worthwhile to measure the compartmental pressures below the knees before the patient is moved from the OR. Below-the-knee two-incision four-compartment fasciotomies are performed when pressures exceed 30 to 35 mm Hg.¹⁴ Three-compartment fasciotomies in the thighs have proved necessary in some surviving patients after caval ligation. Patients who have undergone ligation of the infrarenal inferior vena cava require vigorous resuscitation with crystalloid solutions in the postoperative period; in addition, both lower extremities should be wrapped with elastic compression wraps and elevated for 5 to 7 days after operation. Patients who have some residual edema during the later stages of hospitalization despite the elastic compression wraps should be fitted with

full-length custom-made support hose. Ligation of the suprarenal inferior vena cava is occasionally necessary when the patient has an extensive injury at this location and appears to be in an irreversible shock state during operation.²⁹ If the patient's condition improves during a brief period of resuscitation in the SICU, reoperation and reconstruction with an externally supported PTFE graft are usually necessary to prevent renal failure.

The survival rate in patients with injuries to the inferior vena cava depends on the location of the injury; in the past, it ranged from 60% for the suprarenal vena cava to 78% for the infrarenal vena cava but decreased to approximately 33 to 56% if injuries to the retrohepatic vena cava were included. Current studies indicate survival rates of 22 to 56% for inferior vena cava injuries taken as a whole.^{1-3,30-32} A 2001 review reported survival rates of 46.1% for the infrarenal inferior vena cava and 40.3% for more superior injuries.⁴ In a recent review of 25 patients undergoing ligation of the infrahepatic inferior vena cava (22 infrarenal, three suprarenal), survival was 41%. One-year follow-up was available in seven of nine survivors, and no patient had more than trace edema.³²

Injuries in Zone 2

Hematoma or hemorrhage in zone 2 is cause to suspect the presence of injury to the renal artery, the renal vein, or the kidney.

In patients who have sustained blunt abdominal trauma but in whom preoperative intravenous pyelography, renal arteriography, or abdominal computed tomography (CT) confirms that a reasonably intact kidney is present, there is no justification for opening a perirenal hematoma if one is found at a subsequent operation [see Figure 11].³³

In highly selected stable patients with penetrating wounds to the flank, there are some data to justify performing preoperative CT. On occasion, documentation of an isolated minor renal injury in the absence of peritoneal findings on physical examination makes it possible to manage such patients nonoperatively.³³ In all other patients with penetrating wounds, when a perirenal hematoma is found during initial exploration, the hematoma should be unroofed and

Figure 10 Shown is a polytetrafluoroethylene patch repair of an injury to the infrarenal inferior vena cava.

Figure 11 A right perirenal hematoma was not opened at operation because preoperative abdominal computed tomography documented a reasonably intact kidney.

the wound tract explored. If the hematoma is not rapidly expanding and there is no active hemorrhage from the perirenal area, some surgeons control the ipsilateral renal artery with a Silastic loop in the midline of the retroperitoneum at the base of the mesocolon.^{34,35} Control of the left renal vein can be obtained at the same location; however, control of the proximal right renal vein requires mobilization of the C loop of the duodenum and dissection of the vena cava at its junction with this vessel.

If there is active hemorrhage from the kidney through Gerota fascia or from the retroperitoneum overlying the renal vessels, no central renal vascular control is necessary. In such a situation, the retroperitoneum lateral to the injured kidney should be opened, and the kidney should be manually elevated directly into the abdominal incision. A large vascular clamp should then be applied directly to the hilar vessels of the elevated kidney to control any further bleeding until a decision is reached on repair versus nephrectomy.

On rare occasions, a small perforation of the renal artery can be repaired by lateral arteriorrhaphy or resection with an end-to-end anastomosis.³⁶ Interposition grafting and replacement of the renal artery with either the hepatic artery (on the right) or the splenic artery (on the left) have been used on rare occasions, but such approaches ordinarily are not indicated unless the injured kidney is the only one the patient has. In patients who have sustained multiple intra-abdominal injuries from penetrating wounds or have undergone a long period of ischemia while other injuries were being repaired, nephrectomy is the appropriate choice for a major renovascular injury, provided that intraoperative palpation has confirmed the presence of a normal contralateral kidney.

The role of renal revascularization in patients who have intimal tears in the renal arteries demonstrated on an abdominal CT scan or renal arteriogram after deceleration-type trauma remains controversial. If a circumferential intimal tear is noted on preoperative CT or conventional arteriography but flow to the kidney is preserved, the decision whether to repair the artery depends on whether laparotomy is necessary for other injuries and whether the opportunity for anticoagulation is available. If there are no other significant injuries and flow to the kidney is preserved despite the presence of an intimal tear, anticoagulation and a repeat contrast-enhanced CT within the first several days may be justified. An alternative approach involves insertion of an endovascular stent in the renal artery, followed by a period of anticoagulation (see below).³⁷ If occlusion of the proximal renal artery from blunt deceleration-type trauma is documented, the critical factor for renal salvage is the time from occlusion to revascularization. Renal artery occlusion from deceleration-type trauma that is detected within 6 hours of injury may be treated with immediate operation, resection of the area of intimal damage, and an end-to-end anastomosis performed by an experienced vascular trauma team. Given proper exposure and medial mobilization of the kidney, this operation is not technically difficult in a young trauma patient whose renal artery is otherwise normal. In a 1998 review, fewer than 20% of kidneys revascularized in this manner regained any significant degree of function.³⁸ Hypertension develops in some patients who undergo observation only after thrombosis is detected.

The survival rate in patients with injuries to the renal arteries has been 65% in recent reviews [see Table 2].^{1,3,4}

Many patients with penetrating wounds to the renal veins are quite stable as a result of the retroperitoneal tamponade described earlier (see above). Once vascular control is obtained with the direct application of clamps, lateral venorrhaphy is the preferred technique of repair. If ligation of the right renal vein is necessary to control hemorrhage, nephrectomy should be performed, either at the initial laparotomy or at reoperation after a damage-control laparotomy; the medial left renal vein may be ligated as long as the left adrenal and gonadal veins are intact. It should be noted, however, that in some vascular series, more postoperative renal complications were noted when this maneuver was used on the left side.³⁹

The survival rate in patients with injuries to the renal veins ranged from 44.2 to 70% in three recent reviews, with a mean of 60.4% [see Table 3].^{1,3,4}

Injuries in Zone 3

Hematoma or hemorrhage in either lateral pelvic area is suggestive of injury to the iliac artery or the iliac vein. When lateral pelvic hematoma or hemorrhage is noted after penetrating trauma, compression with a laparotomy pad or the fingers should be maintained as proximal and distal vascular control is obtained. The proximal common iliac arteries are exposed by eviscerating the small bowel to the right and dividing the midline retroperitoneum over the aortic bifurcation. In young trauma patients, the common iliac artery usually is not adherent to the common iliac vein, and Silastic loops can be passed rapidly around these vessels to provide proximal vascular control. Distal vascular control is most easily obtained where the external iliac artery and vein come out of the pelvis proximal to the inguinal ligament. Even with proximal and distal control of the common or the external iliac artery and vein, there is often continued back-bleeding from the internal iliac artery. Such bleeding is controlled by elevating the Silastic loops on the proximal and distal iliac artery and then either clamping or looping the ipsilateral internal iliac artery, which is the only major branch vessel that descends into the pelvis.

For transpelvic bilateral iliac vascular injuries resulting from a penetrating wound, a technique of total pelvic vascular isolation has been described. Proximally, the abdominal aorta and the inferior vena cava are cross-clamped just above their bifurcations, and distally, both the external iliac artery and the external iliac vein are cross-clamped, with one clamp on each side of the distal pelvis. Back-bleeding from the internal iliac vessels is minimal with this approach.

Ligation of either the common or the external iliac artery in a hypotensive trauma patient leads to a greater than 50% amputation rate in the postoperative period; consequently, injuries to these vessels should be repaired if at all possible. The standard options for repair—lateral arteriorrhaphy, completion of a partial transection with an end-to-end anastomosis, and resection of the injured area with insertion of a conduit—are feasible in most situations [see Figure 12].⁴⁰ On rare occasions, it may be preferable either to mobilize the ipsilateral internal iliac artery to serve as a replacement for the external iliac artery or to transpose one iliac artery to the side of the contralateral iliac artery.⁴¹ When a patient is in severe shock from exsanguination caused by a complex injury to the common or the external iliac artery, damage-control

Figure 12 A 24-year-old man experienced a gunshot wound to the left external iliac artery and vein. The arterial injury was repaired with segmental resection and insertion of an 8 mm polytetrafluoroethylene graft; the venous injury was repaired with segmental resection and an end-to-end anastomosis.

laparotomy [see Damage-Control Laparotomy, *below*] is indicated.⁴² The injured area should be resected and a temporary intraluminal Argyle, Javid, or Pruitt-Inahara shunt inserted to maintain flow to the ipsilateral lower extremity during resuscitation in the SICU.¹

One unique problem associated with repair of the common or the external iliac artery is the choice of technique when significant enteric or fecal contamination is present in the pelvis. In such cases, there is a substantial risk of postoperative pelvic cellulitis, a pelvic abscess, or both, which may lead to blowout of any type of repair. When extensive contamination is present, it is appropriate to divide the common or external iliac artery above the level of injury, close the injury with a double row of continuous 4-0 or 5-0 polypropylene sutures, and bury the stump underneath uninjured retroperitoneum. If a stable patient has obvious ischemia of the ipsilateral lower extremity at the completion of this proximal ligation, one may perform an extra-anatomic femorofemoral crossover bypass with an 8 mm externally supported PTFE graft to restore arterial flow to the extremity.¹ If the patient is unstable, one should take several minutes to perform an ipsilateral four-compartment below-knee fasciotomy; this step will counteract the ischemic edema that inevitably leads to a compartment syndrome and compromises the early survival of the leg. After adequate resuscitation in the SICU, the patient should be returned to the OR for the femorofemoral graft within 4 to 6 hours.

Injuries to the internal iliac arteries are usually ligated even if they occur bilaterally because young trauma patients typically have extensive collateral flow through the pelvis.

The survival rate in patients with isolated injuries to the external iliac artery in older series exceeded 80% when tamponade was present. If the injury was large and free bleeding had occurred preoperatively, however, the survival rate was only 45%. Current studies report overall survival rates of approximately 45 to 55% for injuries to the common iliac artery and 62 to 65% for injuries to the external iliac artery [see Table 2].^{1,3,4,43}

Hemorrhage from injuries to the iliac veins can usually be controlled by means of compression with either sponge sticks or the fingers. As noted, division of the right common iliac artery may be necessary for proper visualization of an injury to the right common iliac vein or inferior vena cava at the confluence of the iliac veins. Similarly, ligation and division of the internal iliac artery on the side of the pelvis will yield improved exposure of an injury to an ipsilateral internal iliac vein.⁴⁴

Injuries to the common or the external iliac vein are best treated by a lateral venorrhaphy with continuous 4-0 or 5-0 polypropylene sutures. Significant narrowing often results, and a number of reports have demonstrated occlusion on postoperative venography. For patients with narrowing or occlusion, as well as for those in whom ligation was necessary to control exsanguinating hemorrhage, the use of elastic compression wraps and elevation for the first 5 to 7 days after operation is mandatory.⁴⁵

In some centers, once the patient's perioperative coagulopathy has resolved, anticoagulation with a low-molecular-weight heparin is initiated to prevent progression or migration of a venous thrombus. The patient is then discharged on a regimen of oral warfarin sodium, and serial measurement of the international normalized ratio (INR) is continued for 3 months.

The survival rate in patients with injuries to the iliac veins ranges from 33 to 81%, depending on whether associated vascular injuries are present [see Table 3].^{1-4,42,46} In three recent series, the survival rate (location not specified or combined injury) was 65%.²⁻⁴

Injuries in the Porta Hepatis or Retrohepatic Area

PORTA HEPATIS

Hematoma or hemorrhage in the area of the portal triad in the right upper quadrant is cause to suspect the presence of injury to the portal vein or the hepatic artery or of vascular injury combined with an injury to the common bile duct.

If a hematoma is present, the proximal hepatoduodenal ligament should be occluded with a vascular clamp (the Pringle maneuver) before the hematoma is entered.⁴⁷ If the hematoma is centrally located in the porta, one may also be able to apply an angled vascular clamp or vascular forceps to the distal end of the portal structures at their entrance into the liver.

If hemorrhage is occurring, compression of the bleeding vessels with the fingers should suffice until the vascular clamp is in place. Once proximal and distal vascular control is obtained, the three structures in the hepatoduodenal ligament must be dissected out very carefully because of the danger of blindly placing sutures in proximity to the common bile duct.

Injuries to the common hepatic artery in this location are occasionally amenable to lateral repair, although ligation of the right or left hepatic artery is ordinarily well tolerated because of the extensive collateral arterial flow and perfusion of oxygenated blood through the ipsilateral branch of the portal vein.⁴⁸⁻⁵¹ If an associated hepatic injury calls for extensive suturing or débridement, ligation of the common hepatic artery or artery to the injured lobe will certainly lead to

increased postoperative necrosis of the hepatic repair. Moreover, ligation of the common hepatic artery or the right or left hepatic artery and the portal vein branch to that lobe will lead to necrosis of the lobe and will necessitate hepatectomy. Finally, ligation of the right hepatic artery to control hemorrhage should be followed by cholecystectomy.

Because of the large size of the portal vein and its posterior position in the hepatoduodenal ligament, injuries to this vessel are particularly lethal. Once the Pringle maneuver has been performed, mobilization of the common bile duct to the left and of the cystic duct superiorly, coupled with an extensive Kocher maneuver, allows excellent visualization of any injury to this vein above the superior border of the pancreas. When the perforation extends underneath the neck of the pancreas, it may be necessary to have an assistant compress the superior mesenteric vein below the pancreas and then to divide the pancreas between noncrushing intestinal clamps to obtain exposure of the junction of the superior mesenteric vein and the splenic vein.

The preferred technique for repairing an injury to the portal vein is lateral venorrhaphy with continuous 4-0 or 5-0 polypropylene sutures.^{52,53} Complex repairs that have been successful on rare occasions include end-to-end anastomosis, interposition grafting with externally supported PTFE, transposition of the splenic vein, and a venovenous shunt from the superior mesenteric vein to the distal portal vein or the inferior vena cava. Such vigorous attempts at restoration of blood flow are not justified in patients who are in severe hypovolemic shock, for whom ligation of the portal vein is more appropriate. In addition, if a portosystemic shunt is performed in such a patient, hepatic encephalopathy will result because hepatofugal flow will be present in the rerouted or bypassed portal vein. As with ligation of the superior mesenteric vein, it is necessary to infuse significant amounts of crystalloids to reverse the transient peripheral hypovolemia that occurs secondary to the splanchnic hypervolemia resulting from ligation of the portal vein.^{20,53}

Since the early 1980s, the survival rate in patients with injuries to the portal vein has been approximately 50%.^{1,3,52,53}

RETROHEPATIC AREA

Retrohepatic hematoma or hemorrhage is cause to suspect the presence of injury to the retrohepatic vena cava, a hepatic vein, or a right renal blood vessel. In addition, hemorrhage in this area may signal injury to the overlying liver.

If there is a hematoma that is not expanding or ruptured and clearly has no association with the right perirenal area, a tamponaded injury to the retrohepatic vena cava or a hepatic vein is present. Perihepatic packing around the right lobe of the liver for 24 to 48 hours has been shown to prevent further expansion and should be considered.

If hemorrhage is occurring that does not appear to be coming from the overlying liver, the right lobe of the liver should be compressed posteriorly to tamponade the caval perforation. The Pringle maneuver is then applied, and the surgical and nursing team, the anesthesiologist, and the blood bank are notified. Once the proper instruments and banked blood are in the OR, the overlying injured hepatic lobe or the lobe closest to the presumed site of injury is mobilized by dividing the triangular and coronary ligaments and then lifted

out of the subdiaphragmatic area.⁵⁴ On occasion, an obvious perforation of the retrohepatic or suprahepatic vena cava or an obvious area where a hepatic vein was avulsed from the vena cava may be grasped with a forceps or a series of Judd-Allis clamps; a Satinsky clamp may then be applied.²⁴ Because of the copious bleeding that occurs as the liver is lifted and the hole in the vena cava sought, the anesthesiologist should start blood transfusions as the lobe is being mobilized.

If the retrohepatic hemorrhage is not controlled after one or two direct attempts, another technique must be tried. The most common choice is the insertion of a 36 French chest tube or a 9 mm endotracheal tube as an atriocaval shunt.⁵⁵ The shunt can reduce bleeding by 40 to 60%, but vigorous hemorrhage persists until full control of the perforation is obtained with clamps or sutures. An alternative approach is to isolate the liver and the retrohepatic vena cava by cross-clamping the supraceliac aorta, the porta hepatis, the suprarenal inferior vena cava, and the intrapericardial inferior vena cava.⁵⁶ Because profoundly hypovolemic patients usually cannot tolerate cross-clamping of the inferior vena cava, this approach is rarely employed. Some experienced hepatic surgeons have successfully used extensive hepatotomy to expose and repair an anterior perforation of the retrohepatic vena cava.⁵⁷

The retrohepatic vena cava is repaired with continuous 4-0 or 5-0 polypropylene sutures. When the atriocaval shunt is removed from the heart after the vessel has been repaired, the right atrial appendage is ligated with a 2-0 silk tie.

The survival rate in patients not in cardiac arrest who undergo atriocaval shunting and repair of the retrohepatic vena cava has ranged from 33 to 50%.^{55,56}

Damage-Control Laparotomy

Patients with injuries to the great vessels of the abdomen are ideal candidates for damage-control laparotomy⁵⁸: they are uniformly hypothermic, acidotic, and coagulopathic on completion of the vascular repair, and a prolonged operation would lead to their demise. Shunting, repair, or ligation of this abdominal vascular injury, packing of minor or moderate injuries to solid organs, packing of the retroperitoneum, stapling and rapid resection of multiple injuries to the GI tract, and consideration of diffuse intra-abdominal packing are all appropriate, as is silo coverage of the open abdomen, in which a temporary silo made from a urologic irrigation bag is sewn to the skin edges with a continuous 2-0 polypropylene or nylon suture.^{59,60}

The patient is then rapidly moved to the SICU for further resuscitation. Priorities in the SICU include rapid restoration of normal body temperature and administration of red blood cells, fresh frozen plasma, and platelets in the military paradigm of "1:1:1" and cryoprecipitate when indicated.⁶¹ It is usually possible to return the patient to the OR for removal of clot and packs, reconstruction of the GI tract, irrigation, and reapplication of silo coverage or application of a vacuum-assisted closure device within 48 to 72 hours.^{59,60}

When massive distention of the midgut persists after 10 to 14 days of intensive care and use of the vacuum-assisted closure device (10 to 25% of patients), the safest approach is to convert the patient to an open abdomen (i.e., without closure of the midline incision) and cover the midgut with a double-thickness layer of absorbable mesh. With proper nutritional support and occasional use of Dakin solution to minimize bacterial contamination of the absorbable mesh, most patients

are ready for the application of a split-thickness skin graft to the eviscerated midgut within 3 to 4 weeks of the original operation for an injury to a great vessel.

Endovascular Therapies

Endovascular techniques are now used selectively in patients with traumatic and iatrogenic abdominal vascular injuries. Examples of arterial repairs in zone 1 have included the insertion of endostents in patients with the following injuries: (1) blunt intimal injuries in the abdominal aorta,^{62–64} (2) late hemorrhage from the abdominal aorta and a hostile abdomen,^{65,66} and (3) the presence of an aortocaval fistula.^{67,68} Even with the obvious concern about thrombosis of endostents placed in the abdominal venous system, such repairs have been performed with injuries to the inferior vena cava.^{69–71}

In zone 2, where angiographic techniques have long been used to control bleeding from or fistulas in the renal parenchyma after trauma,^{72,73} wall stents are now used routinely to control intimal flaps in blunt injuries to the renal arteries.^{74–76}

A significant number of patients with endostent or endograft treatment of iatrogenic and traumatic injuries to the iliac arteries in zone 3 have now been reported.^{77–79} The endostents have been particularly useful in controlling intimal injuries from blunt trauma to the iliac arteries.

Complications

Besides those already mentioned, major complications associated with repair of injuries to the great vessels in the

abdomen include thrombosis, dehiscence of the suture line, and infection. Because of the risk of occlusion of repairs in small vasoconstricted vessels (e.g., the superior mesenteric artery), it may be worthwhile to perform a second-look operation within 12 to 24 hours if the patient's metabolic state suggests that ischemia of the midgut is present. Early correction of an arterial thrombosis in the superior mesenteric artery may permit salvage of the midgut.

As noted [see Injuries in Zone 1, *above*], dehiscence of an end-to-end anastomosis or a vascular conduit inserted in the proximal superior mesenteric artery when there is an injury to the adjacent pancreas may be prevented or the incidence lowered by inserting a distal aorta–superior mesenteric artery bypass graft. To prevent adjacent loops of small bowel from adhering to the vascular suture lines, both lines should be covered with soft tissue (retroperitoneal tissue or omental pedicle for the aortic suture line and mesenteric tissue for the superior mesenteric arterial suture line). Also as noted [see Injuries in Zone 3, *above*], when an extensive injury to either the common or the external iliac artery occurs in the presence of significant enteric or fecal contamination in the pelvis, ligation and extra-anatomic bypass may be necessary.

On occasion, vascular-enteric fistulas occur after repair of the anterior aorta or the insertion of grafts in either the abdominal aorta or the superior mesenteric artery.¹ In my experience, such fistulas most commonly occur at suture lines; hence, proper coverage of suture lines with soft tissue should eliminate or lower the incidence of this complication.^{22,80}

11 INJURIES TO THE UROGENITAL TRACT

Alex J. Vanni, MD, and Hunter Wessells, MD, FACS

The World Health Organization (WHO) predicts a dramatic worldwide rise in the burden of disease caused by road traffic accidents and war.¹ This rise will directly influence the incidence of urogenital trauma, in that motor vehicle crashes (MVCs) and firearm injuries are responsible for the overwhelming majority of major renal and pelvic injuries.² In one population-based study, the percentage of trauma patients in the United States who had renal injuries was 1.2% (incidence 4.9 per 100,000 population).³ Thus, in 1 year, some 14,000 patients with renal injuries are hospitalized nationwide. Approximately 45,000 pelvic fractures occur each year in the United States, 15 to 25% of which are associated with urologic injury. Urogenital injuries, although rarely fatal, can cause profound morbidity and permanently impair quality of life. Early identification and treatment can reduce the long-term disability associated with these injuries.

Blood in the urine is the hallmark of injury to the urogenital system; however, as an isolated indicator, it is not specific for injury location or severity. In penetrating abdominal trauma, hematuria is a signal that the kidneys, the ureters, and the bladder must be evaluated. Urethral and genital injuries are suspected only in the setting of wounds to the pelvis, the perineum, or the buttocks. When hematuria occurs in association with blunt trauma, the entire urogenital system must be evaluated: the forces associated with high-speed MVCs and falls can cause injuries to both the upper and the lower regions of the urogenital tract.

In what follows, each of the major urogenital organs is treated separately. New imaging modalities and a growing emphasis on nonoperative management of upper and lower urinary tract injuries have dramatically changed the field of urologic trauma. Concomitant injury to both the upper and the lower urinary tract is rare, but extra vigilance must be maintained to detect such injury when it does occur. Evaluation and management of trauma to the female reproductive organs require special expertise, particularly when the patient is the victim of a sexual assault.

Injuries to the Kidneys

INITIAL EVALUATION

The most reliable sign of injury to the kidney is hematuria [see Figure 1], except in patients with renal artery thrombosis or pedicle avulsion, who may have no blood in their urine. However, the degree of hematuria correlates poorly with the severity of renal injury,⁴ and as a result, criteria for imaging in these patients must take into account both the mechanism of injury and the probability of severe kidney injury.⁵ Accordingly, a consensus statement from a renal trauma subcommittee convened by the WHO proposed guidelines for imaging

renal injuries [see Table 1].⁶ As with all guidelines, exceptions exist. A high degree of suspicion for renal trauma is required for patients who do not meet the hematuria criteria for imaging but who have experienced a fall from a height, have sustained a direct blow to the flank, or have other indicators (e.g., persistent flank pain or severe associated injuries).

Computed tomography (CT) is the first-line imaging modality for all cases of suspected renal trauma in hemodynamically normal and stable patients. A standard examination includes helical (spiral) CT with a portal venous phase (from the diaphragm to the ischial tuberosities) to visualize active arterial bleeding [see Figure 2a], followed after 10 minutes by delayed images (from the kidneys to the ischial tuberosities) to identify urinary contrast extravasation [see Figure 2b]. CT should not be used as the primary evaluation method in hemodynamically unstable patients: other diagnostic tests, such as diagnostic peritoneal lavage (DPL) or ultrasonography, should be performed before renal imaging with CT.

The American Association for the Surgery of Trauma (AAST) Organ Injury Scale is used to classify blunt and penetrating renal injuries and corresponds closely to the appearance of the kidney on CT [see Figure 3 and Table 2].⁷

MANAGEMENT

Differences in the management of blunt and penetrating renal trauma are a result of the greater instability of the patient after penetrating trauma and the higher likelihood of severe renal injuries after firearm and stab wounds.

Nonoperative

The goal in the management of renal trauma is to safely preserve the maximal number of renal units, avoiding unnecessary explorations, repairs, and nephrectomies. Increasing numbers of renal injuries, including grade IV and V injuries, are being managed nonoperatively. The accuracy and rapidity of helical CT, combined with the improvements achieved in resuscitation methods, have reduced the number of renal explorations performed.⁸ Currently, 36% of all penetrating renal injuries and fewer than 5% of blunt injuries necessitate operative management.⁹ All grade I and II renal injuries, regardless of the mechanism of injury, can be managed with observation alone because the risk of delayed bleeding is extremely low. Most grade III and IV injuries, including those with devitalized parenchymal fragments and urinary extravasation, can be managed nonoperatively with close monitoring, serial hematocrit measurement, and repeat imaging in selected cases. Active arterial bleeding, in the absence of other associated injuries, can be treated with emergency arteriography and selective angioembolization.

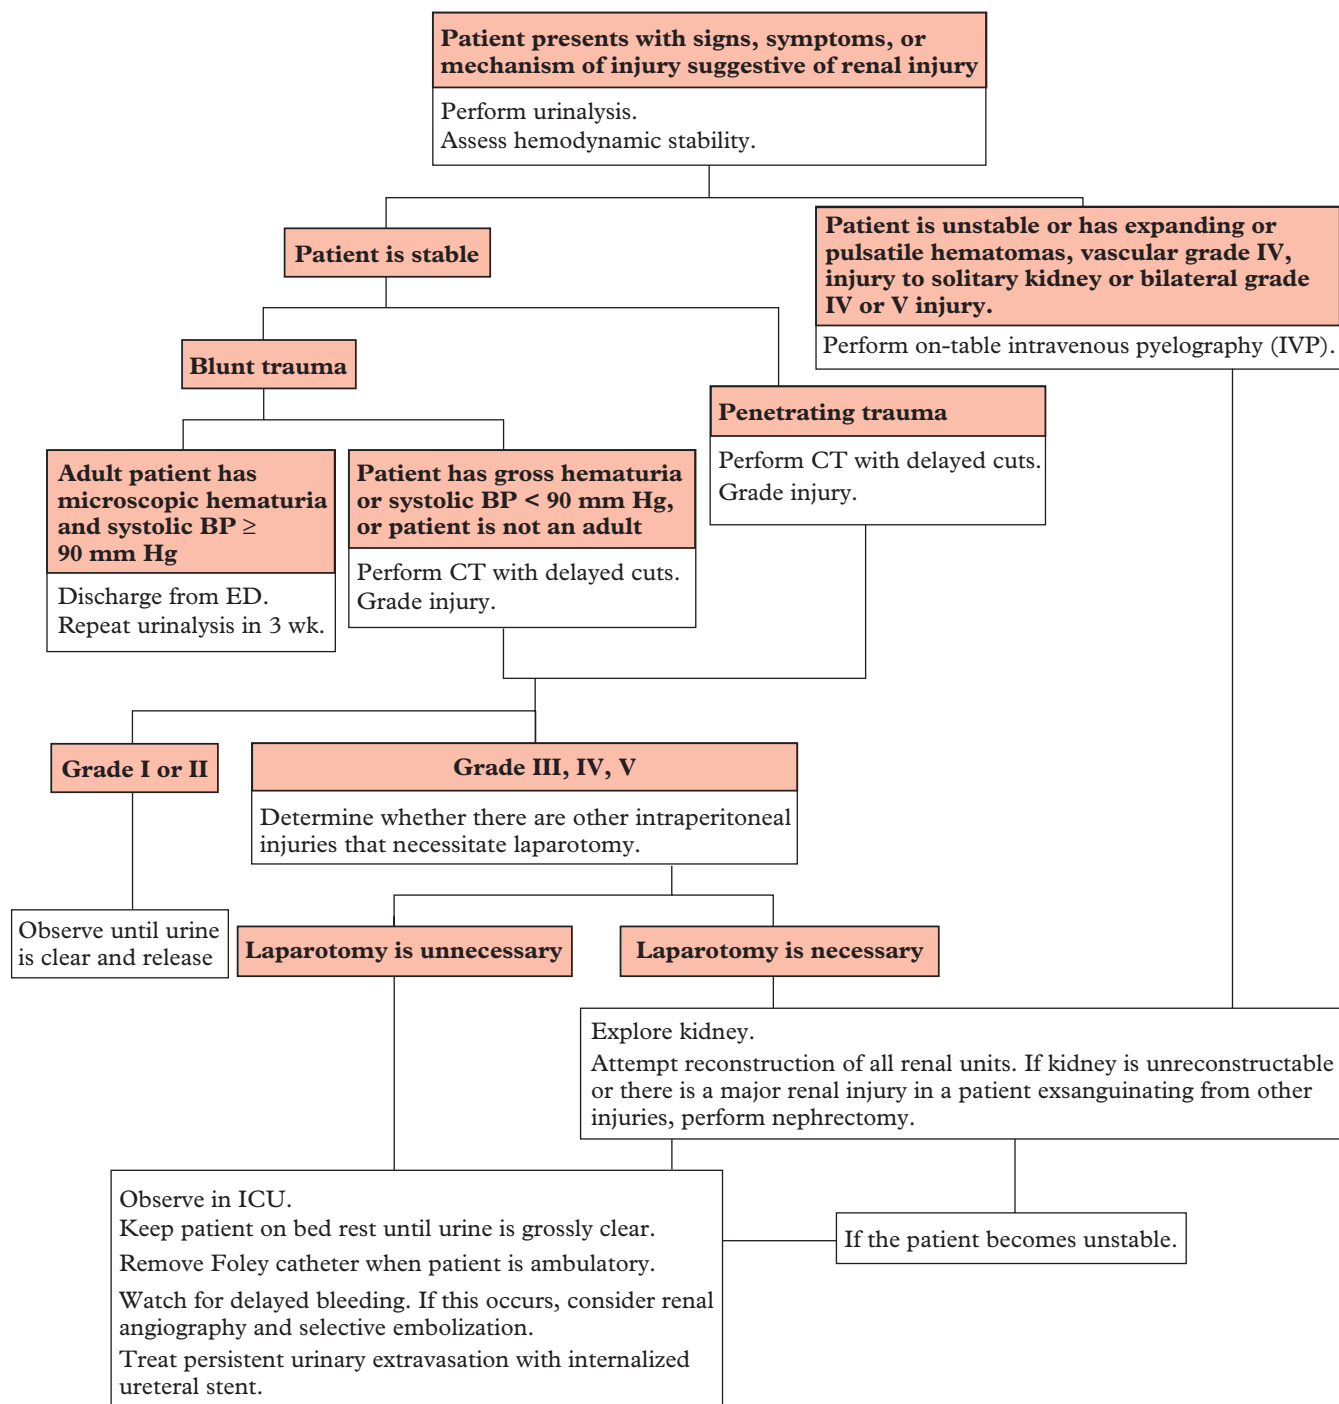

Figure 1 Algorithm outlining management of renal injuries. BP = blood pressure; CT = computed tomography; ED = emergency department; ICU = intensive care unit.

Thrombosis of the renal artery or its branches is treated expectantly unless the contralateral kidney is absent or injured, in which case, emergency revascularization is indicated. Endoluminal stenting and thrombolytic therapy are promising but still experimental approaches with limited long-term follow-up.^{10,11}

Critics of nonoperative management cite the potential risk of delayed complications avoided by nephrectomy or renorrhaphy. To date, there are no prospective, randomized, controlled trial data comparing operative versus nonoperative management of renal trauma injuries. However, a number of studies have shown a decrease in the number of renal

Table 1 Criteria for Imaging of Renal Injuries	
Type of Trauma	Criteria for Imaging
Blunt	Gross hematuria (visibly blood-tinged urine)
	Adult with microhematuria (defined as ≥ 1 + RBC on dipstick or > 3 RBC/hpf) with a period of hypotension (systolic BP < 90 mm Hg)
	Child (< 15 yr) with > 50 RBC/hpf
Penetrating	Stable patient with any degree of hematuria and injury near urinary tract

hpf = high-power field; RBC = red blood cells.

explorations performed with minimal morbidity and without increasing mortality.¹²

Operative

The only absolute indications for renal exploration are pedicle avulsion, pulsatile or expanding hematoma, and hemodynamic instability resulting from renal injury.⁶ Significant numbers of shattered kidneys (grade V) and renal vascular injuries (grades IV and V) are now managed nonoperatively. The strongest predictor for nephrectomy is severity of renal injury; however, roughly one third of all penetrating and 44% of blunt grade IV and V renal injuries are now managed nonoperatively.^{9,13,14} In patients who require laparotomy for associated injuries, renal exploration and reconstruction of grade III and IV injuries may reduce the likelihood of delayed complications. However, the need for laparotomy and surgery for other intra-abdominal organs is associated with a higher likelihood of nephrectomy. Thus, exploration of suspected kidney injuries (as determined by previous imaging or on-table evaluation) in patients undergoing laparotomy for major splenic or bowel injury should be attempted by surgeons experienced in repairing an injured kidney.⁹ In reality, the success of nonoperative management for most grade III and IV injuries means that operative intervention

in cases of blunt trauma is typically limited to patients with the most severe renal injuries, in whom conservative management fails either because of bleeding or because of ongoing urinary extravasation despite ureteral stenting.¹⁵

A significant number of patients with a penetrating injury and a minority of those with blunt trauma require immediate laparotomy before radiographic evaluation.^{9,13} Hematuria should alert the surgeon to the possibility of renal injury, and the presence of a perinephric hematoma visible through the mesocolon should prompt further evaluation. If a major renal injury is suspected on the basis of the size of the hematoma or an abnormal intraoperative intravenous pyelogram (IVP), exploration is indicated.

Intraoperative IVP (so-called one-shot IVP) is indicated when exploration of a kidney is planned and no preoperative imaging is available. The main purpose of a one-shot IVP in this setting is to confirm the presence of a contralateral functioning kidney; a potential benefit is the ability to rule out major injury. The plain abdominal film is obtained 10 minutes after injection of a 150 mL bolus of iodinated contrast material. If the injured kidney is adequately imaged and found to be normal, exploration may be omitted¹⁶; otherwise, the kidney should be explored. In critically ill patients with multiple associated injuries, renal exploration is indicated only if a pulsatile or expanding hematoma is present, in which case, expeditious nephrectomy is necessary. If exploration is not done, staging with CT should be completed once the patient is stable; angioembolization and percutaneous drainage can be used to manage bleeding and urinary extravasation, respectively.^{17–19}

The priorities of operative management for grade III, IV, and V injuries are hemorrhage control and definitive repair of the collecting system. A midline transabdominal incision permits exploration of the kidneys and provides optimal access to the renal hilum. After intraperitoneal sources of bleeding have been controlled, preliminary isolation of the renal artery and vein should be achieved before Gerota's fascia is opened. There is some controversy regarding the value of early vascular control, with one randomized controlled trial showing no benefit from

Figure 2 Shown are (a) a deep laceration with vascular contrast extravasation (arrow) and (b) a deep laceration with urinary contrast extravasation (arrow).

Figure 3 Illustrated is the American Association for the Surgery of Trauma (AAST) classification of renal injuries into grades I through V.

early isolation of the vessels in cases of renal gunshot wounds²⁰; however, the weight of the remaining evidence suggests that this technique is still valuable if renal reconstruction is the goal of exploration with an expected renal salvage rate of 85%.^{6,21,22} Isolation of the renal vessels is accomplished by opening the posterior peritoneum medial to the inferior mesenteric vein or by reflecting the ipsilateral colon (provided that the perinephric hematoma is left undisturbed).

Once vessel loops have been placed around the renal artery and vein, Gerota's fascia is opened. If massive bleeding occurs when the hematoma is entered, Rumel tourniquets or vascular clamps are applied to occlude the renal artery. If this maneuver does not stop the bleeding, one should suspect a venous injury and occlude the renal vein as well. Surface cooling of the kidney is not advocated, because of time constraints and concerns about possibly exacerbating hypothermia. Total exposure of the kidney by means of sharp and blunt dissection facilitates identification of injury to the parenchyma, the renal pedicle, or the collecting system. The renal capsule should not be pulled off the parenchyma: doing so would complicate subsequent repair.

Renal reconstruction includes sharp débridement of all devitalized tissue, achievement of hemostasis, closure of the collecting system, coverage of the defect, and drainage [see Figure 4]. Renal salvage should be possible in nearly 90% of grade III and IV injuries. Nephrectomy is reserved for destroyed kidneys that cannot be reconstructed or for cases of serious renal injury associated with other life-threatening injuries (e.g., vascular or hepatic trauma) in which taking the time required for attempted renal repair would jeopardize the life of the patient.^{3,22,23}

A number of sophisticated products are available for enhancing surgical hemostasis and reducing the need for tedious ligation of individual small arterioles on the parenchymal surface. Such products include a hemostatic bandage applied directly to the cut surface of the kidney,²⁴ polyethylene glycol-based hydrogels, fibrin glue, and a gelatin matrix–thrombin tissue sealant (FloSeal, Baxter International, Inc., Deerfield, IL).^{25–28} To date, none of these products have been evaluated in the setting of blunt renal injuries, but the results in elective partial nephrectomy models are encouraging.²⁸

Table 2 AAST Organ Injury Scales for Urinary Tract

Injured Structure	AAST Grade	Characteristics of Injury	AIS-90 Score
Kidney*	I	Contusion with microscopic or gross hematuria, urologic studies normal; nonexpanding subcapsular hematoma without parenchymal laceration	2; 2
	II	Nonexpanding perirenal hematoma confined to renal retroperitoneum; laceration < 1.0 cm parenchymal depth of renal cortex without urinary extravasation	2; 2
	III	Laceration > 1.0 cm parenchymal depth of renal cortex without collecting system rupture or urinary extravasation	3
	IV	Parenchymal laceration extending through renal cortex, medulla, and collecting system; injury to main renal artery or vein with contained hemorrhage	4; 4
	V	Completely shattered kidney; avulsion of renal hilum that devascularizes kidney	5; 5

AAST = American Association for the Surgery of Trauma; AIS-90 = Abbreviated Injury Score, 1990 version.

*Advance one grade for bilateral injuries, up to grade III.

†Advance one grade for multiple injuries, up to grade III.

Once hemostasis is satisfactory, the collecting system is scrutinized for evidence of injury. If the extent of the injury is unclear, 2 to 3 mL of methylene blue is directly injected into the renal pelvis while the ureter is occluded with a vessel loop to identify any openings in the collecting system. Open calyces or infundibula are closed with 4-0 absorbable sutures, whereas the renorrhaphy is completed with interrupted 2-0 absorbable sutures. Often the renal capsule can be used to cover exposed renal parenchyma and provide additional hemostasis. The defect in the parenchyma can be filled with folded absorbable gelatin sponges as the capsule is closed over the bolsters. If the capsule has been destroyed, coverage may be obtained with an omental or perinephric fat flap tacked down over the defect, a patch constructed from polyglycolic acid or peritoneum, or an entire sac of polyglycolic acid wrapped around the kidney, with the parenchymal edges kept well apposed.²⁹

At the end of the procedure, the kidney is returned to its location within Gerota's fascia, which is not reapproximated. Closed-suction drainage of the renal fossa is recommended only after repair of the collecting system; internalized stents are

reserved for complex injuries (e.g., large lacerations of the renal pelvis or the ureteropelvic junction [UPJ]).

Postintervention Care

Management of patients after operative or nonoperative intervention for renal trauma depends to a large extent on the presence and severity of associated injuries. The most significant urologic complications are urinary leakage, urinoma formation, and delayed bleeding.

After nonoperative management Bed rest is prescribed until the urine becomes grossly clear. Drainage of the bladder with a Foley catheter is necessary only until other injuries are stable and the patient can void spontaneously. For grade IV injuries with large amounts of urinary extravasation, follow-up imaging 48 to 72 hours after the initial scan is recommended to evaluate the degree of ongoing extravasation.^{15,30} CT is recommended, although in children, protocols that reduce the radiation exposure should be used. If at 72 hours the amount of extravasation has not decreased from

Figure 4 Depicted are the steps in renal reconstruction. (a) The patient has suffered a deep midrenal laceration into the renal pelvis. If the renal capsule is present at the wound margins, it should be peeled back and preserved for subsequent closure. The devitalized renal parenchyma is removed with a scalpel until bleeding occurs at the margin. Polar injuries can be débrided by guillotine amputation of the parenchyma. (b) The collecting system having been closed, vessels are ligated. Manual compression usually controls bleeding during ligation. Ligation of individual vessels with absorbable monofilament suture material achieves hemostasis. Temporary release of renal artery occlusion for the assessment of hemostasis is not recommended. Ligation of venous bleeding points generally controls adjacent arterial sources. (c) Sutures are placed to close the defect. (d) An absorbable gelatin sponge is placed. (e) Alternatively, the defect may be closed with an omental pedicle flap.

that seen on the initial scan, stenting is indicated. The presence of urinary extravasation within or outside Gerota's fascia is inconsequential in the decision to proceed with renal exploration or ureteral stenting. Cystoscopy and internal double J stenting allow successful treatment of the small percentage of cases in which the injury does not close spontaneously.³⁰ When a double J stent is used to manage persistent extravasation, the urinary bladder should be decompressed with a Foley catheter.

Parenchymal fragmentation and arterial thrombosis cause ischemia and often delay resolution of urinary leakage.³¹ Nevertheless, internal stenting almost invariably suffices, although resolution of extravasation can take weeks to months. Ultrasonography is useful for following such collections and for reducing the patient's radiation exposure. For small uninfected collections adjacent to the kidney, no intervention is needed. If a perinephric fluid collection is large enough to compress the ureter or becomes infected, additional percutaneous drainage is indicated [see Figure 5]. The drain fluid is tested for creatinine, and if the findings are consistent with a urine leak, the drain is left in place until the collection resolves

and leakage can no longer be demonstrated on contrast imaging.

Delayed bleeding is a rare but serious complication of nonoperative management of major lacerations.³² Pseudoaneurysm formation is the most common cause of delayed bleeding [see Figure 6].³³ Gross hematuria usually, but not invariably, accompanies the bleeding. If it is seen in conjunction with hypotension or a decreasing hematocrit, urgent angiography is the best initial approach; selective embolization is an effective treatment that renders exploration unnecessary in most instances.

Nonspecific low-grade fever, flank pain, and elevated white blood cell count can be seen with nonoperative renal injury management; thus, care must be taken to exclude an infected retroperitoneal hematoma or urinoma.

After operative management Retroperitoneal drains are removed within 48 hours after renal exploration unless the creatinine concentration in the drained fluid is higher than that in the serum. Persistent urinary leakage is best evaluated by means of repeat CT with delayed cuts. As with

Figure 5 Computed tomographic scan showing an infected urinoma in a patient with left grade IV injury who presented 7 days after injury with fever and sepsis and subsequently underwent ureteral stenting. The urinoma was drained percutaneously.

nonoperative management, internal stenting and percutaneous drainage are the mainstays of treatment for leaks and urinomas, respectively. Postoperative hemorrhage is rare if the injured parenchyma has been adequately débrided and repaired. Angiographic evaluation with embolization is the best approach for postoperative renal bleeding.

Functional Imaging

Postoperative nuclear imaging correlates with AAST renal injury grade and is recommended in patients with grade IV and V injuries involving significant parenchymal loss or

Figure 6 Shown is a pseudoaneurysm of the left kidney after blunt injury.

vascular injury.³⁴ The goal is to identify patients with significant loss of functioning renal tissue who are at potential risk for chronic renal insufficiency. Grade III, IV, and V renal injuries result in a mean decrease in renal function of 15%, 30%, and 65% respectively.³⁴ Patients whose level of residual function in the injured kidney, as determined by radionuclide scintigraphy, is less than 25% should be considered as having a solitary kidney. This information is useful in counseling patients who participate in high-risk sports activities (e.g., skydiving, motocross, and hang gliding). The optimal timing of postoperative nuclear imaging has not been determined, but by 3 months, the hematoma and inflammation related to the injury usually have resolved.

Hypertension is a rare late complication of renal reconstruction and nonoperative management, usually renin mediated and deriving from an ischemic segment of renal parenchyma (also referred to as a Goldblatt kidney). Occasionally, angiography delineates the ischemic segment of the kidney, and excision of the nonperfused segment or complete nephrectomy may be required.

Injuries to the Ureters

INITIAL EVALUATION

Ureteral trauma [see Table 2] is rare, accounting for fewer than 1% of genitourinary injuries. Furthermore, the absence of physical signs of injury makes diagnosis difficult, and a delayed presentation is not uncommon. Gross or microscopic hematuria may be absent in 25 to 83% of patients with ureteral injuries, and as many as one half of all ureteral injuries resulting from blunt trauma are not recognized immediately. A high index of suspicion and a high degree of vigilance are necessary if the diagnosis is to be made early enough to prevent late consequences such as urinoma, sepsis, and nephrectomy.^{35–37}

The mechanism of injury has a particular bearing on the diagnosis and management of ureteral injury. The complexity of ureteral repair and number of associated injuries increase with the severity of AAST grade.³⁷ Overall, penetrating wounds are the predominant cause of these injuries. CT with delayed cuts should be performed when ureteral injury is suspected and the patient is stable. Imaging is of variable usefulness in the detection of ureteral injuries, but extravasation of the contrast agent is diagnostic.³⁸ Only 4 to 20% of ureteral injuries are caused by blunt trauma, and within this category, MVCs predominate.^{35,37} In children, ureteral injury at the UPJ often occurs after severe deceleration.³⁹ Children's ureters are particularly prone to injury at this location because the hyperextensibility of their spines can result in ureteral avulsion at the UPJ.^{37,38,40}

MANAGEMENT

All injuries to the ureter should be repaired surgically [see Figure 7] unless a delay in diagnosis has resulted in an abscess or a urinoma [see Figure 8]. If an abscess or a urinoma is present, drainage by means of percutaneous nephrostomy, coupled with ureteral stenting, allows infection and inflammation to resolve before definitive management; in this setting, an operative approach is likely to result in nephrectomy.

Figure 7 Algorithm outlining management of ureteral injuries. CT = computed tomography.

Ureteral Exploration

In stable patients, blunt ureteral injuries are typically identified by preoperative radiographic studies, which allow directed exploration and repair (see below). With penetrating trauma, ureteral injury may not be suspected until the time of laparotomy, when a hematoma is found near the kidney or ureter. Direct inspection of the entire trajectory of the offending agent requires particular vigilance for direct injury to or contusions of the ureter. Injection of indigo carmine into the collecting system identifies extravasation. Direct injection saves time and ensures that injuries are not missed as a result of low urine output from shock or renal injury. One study found that all penetrating ureteral injuries were detected at laparotomy without previous imaging.³⁶

Figure 8 Computed tomographic scan showing extravasation and urinoma caused by unrecognized right upper ureteral injury.

Reconstruction and Repair

Ureteral injuries should undergo surgical reconstruction as soon as they are recognized unless associated injuries prevent such a strategy. For example, gunshot injuries to the iliac vessels or the ureters may necessitate heroic vascular reconstruction. Ligation of the ureter with subsequent nephrostomy tube drainage or exteriorization of a ureteral stent allows elective reconstruction months later. Percutaneous and endoscopic approaches can also be used to establish urinary drainage if ureteral exploration is not feasible.

In the event that the operating surgeon is unfamiliar with acute ureteral reconstruction, several options are available before definitive repair. One option is to exteriorize a ureteral stent, suturing the ureter to the stent with a 2-0 silk suture, to facilitate locating the ureter during subsequent delayed reconstruction. Another approach is to ligate the injured ureter with a 2-0 silk suture with subsequent percutaneous nephrostomy tube drainage. An 8 French nephrostomy tube should be placed in the ipsilateral kidney after the patient has been stabilized to ensure maximal urinary drainage, avoiding the complications of urinary infection and nephron loss. No trauma data exist defining the maximum safe time interval of ureteral ligation on kidney function; however, timely nephrostomy tube placement after occlusion is likely to minimize potential complications secondary to obstruction. Once urinary drainage has been attained with either a ureteral stent or nephrostomy tube, definitive ureteral reconstruction by an experienced urologist should be performed within the first few days after injury or else delayed for a minimum of 3 months, or longer, until the patient has fully recovered.

Reconstructive steps in ureter repair include débridement of devitalized tissue, creation of a spatulated tension-free anastomosis, watertight mucosal approximation (5-0 or 6-0 absorbable sutures—knots inside or outside), stenting, coverage of the repair with vascularized tissue when feasible, and appropriate drainage.⁴¹ Stab wounds generally cause less

tissue damage than gunshot wounds and are more easily repaired; partial transections may be closed primarily.

Upper ureter Disruption or transection of the upper ureter or the UPJ is repaired by means of débridement and primary anastomosis of the renal pelvis and the ureter. Mobilization of the ureter is limited to ensure that the blood supply is not compromised. Interrupted 5-0 or 6-0 absorbable sutures are preferred, and a double J ureteral stent or a nephrostomy tube is inserted before completion of the anastomosis.

Medial ureter Injuries to the abdominal ureter between the UPJ and the pelvic brim are repaired by means of ureteroureterostomy [see Figure 9]. After débridement, the ends are spatulated on opposite sides, and an interrupted approximation is completed with 5-0 or 6-0 absorbable sutures over a double J stent. In cases of overlying colonic, duodenal, or pancreatic injury, the anastomosis should be covered with omentum or retroperitoneal fat. Large defects

in the abdominal ureter may necessitate transureteroureterostomy, in which the injured ureter is passed behind the mesocolon to the contralateral side. Anastomosis of the injured ureter to a 1 to 2 cm opening in the medial side of the normal ureter can be achieved without tension. With transureteroureterostomy, a stent (usually a 5 French pediatric feeding tube) should cross the anastomosis and be brought out through the normal lower ureter or bladder.

Distal ureter Ureteral injuries in the pelvis should be managed with reimplantation into the bladder. The distal stump is ligated, and after the anterior bladder wall is opened, the proximal end of the ureter is brought through a new hiatus on the back wall of the bladder. The ureter is then spatulated and approximated to the bladder mucosa with interrupted chromic sutures. One 3-0 anchoring stitch brings the distal apex of the ureter to the muscle and mucosa; the rest of the sutures approximate the mucosa. A refluxing reimplantation is acceptable in adults. Larger defects can be bridged by performing a vesicopsoas hitch, in which the bladder is sewn to the central tendon of the psoas muscle. The dome is mobilized by dividing the obliterated umbilical arteries bilaterally and, if necessary, the contralateral superior vesical artery. Three interrupted nonabsorbable sutures that enter the detrusor muscle (but not the bladder lumen) anchor the dome above the iliac vessels. Complex bladder or vascular injuries in the pelvis make transureteroureterostomy a more attractive option for avoiding further dissection in the injured area. A ureteral stent should be used in all ureteral reimplantations. The bladder is closed in two layers with a continuous 2-0 absorbable suture. Closed-suction retroperitoneal drainage and Foley catheter decompression of the bladder are essential.

Postintervention Care

Postoperative care of ureteral trauma relates mainly to the manipulation of drains and the management of complications. Retroperitoneal drains may have significant output for several days but are removed after 2 to 3 days unless output is consistent with a urine leak as determined by creatinine measurement (see above). Bladder catheterization is necessary for 7 days after ureteral reimplantation. In combined bladder and ureteral reconstructions, contrast cystography is indicated before catheter removal. Cystoscopic removal of the double J stent is usually performed with local anesthesia 4 to 6 weeks after operation. CT, IVP, or renal scintigraphy 3 months after removal of the stent rules out the possibility of asymptomatic obstruction.

Fistula formation, usually the result of distal obstruction or necrosis of the ureter, should be managed by means of antegrade or retrograde drainage of the collecting system with percutaneous or endoscopic techniques. Drainage of periureteral fluid collections may also be necessary. If recognition of an injury or a complication is delayed, reconstruction should be deferred for at least 3 to 6 months until all inflammation has subsided.

Injuries to the Bladder

INITIAL EVALUATION

Bladder injury [see Table 2] is most often caused by blunt injuries, with penetrating trauma accounting for 14 to 33%

Figure 9 Depicted are the steps in a ureteroureterostomy. (a) The injured ureter is dissected free. (b) The ends are débrided and spatulated. (c) A stent is placed, and the anastomosis is begun. (d) The anastomosis is completed.

of civilian cases. About 3 to 9% of patients with a pelvic fracture have an associated injury to the bladder, with an elevated risk of bladder rupture occurring in disruptions of the bony pelvic ring.^{42,43} Because the fracture type has a poor predictive value for the type of associated genitourinary trauma, all patients with pelvic fractures and any degree of hematuria should be suspected of having a bladder injury. Approximately two thirds of bladder injuries are extraperitoneal and one third are intraperitoneal, a distinction that has important management ramifications.

The signs and symptoms of bladder injury are generally nonspecific [see Figure 10], although 95% of patients with bladder rupture present with gross hematuria. Patients may complain of suprapubic pain, dysuria, or an inability to void. Physical examination may reveal tenderness in the suprapubic region, ileus, or an acute abdomen. The percentage of patients without any hematuria ranges from 0 to 3%.^{44,45} Laboratory studies are usually inconclusive unless significant reabsorption of urine causes elevated serum creatinine levels, hyperkalemia, or hyponatremia.⁴⁶

Bladder rupture can be accurately diagnosed with either retrograde CT cystography or plain-film retrograde cystography. The indications for cystography include blunt trauma with gross hematuria in the presence of low-density free abdominal fluid on CT (< 25 HU); blunt trauma with a pelvic ring fracture and any degree of hematuria (> 30 red blood cells [RBCs] per high-power field [hpf]); stable penetrating trauma with any degree of hematuria; and an injury to the pelvis. The appearance of intraperitoneal and extraperitoneal rupture with each modality is characteristic [see Figure 11]. CT cystography is performed with 5 mm cuts after the bladder is filled. Contrast is instilled to tolerance in responsive patients, whereas 40 cc of water and 350 cc of contrast agent are instilled in intubated patients as insufficient bladder filling can yield false negative results. At one large center, the sensitivity and specificity of CT cystography for bladder rupture caused by blunt trauma were 95% and 100%, respectively.⁴⁵ With current patterns of CT use for trauma evaluation, including imaging of pelvic bony fractures, CT cystography appears to be more efficient than plain-film studies. Furthermore, CT cystography clearly identifies the location of many bladder injuries and may be able to identify bladder neck injuries [see Figure 11a]. With penetrating trauma, there must be a higher level of suspicion for bladder injury because the sensitivity and specificity of cystography (CT or conventional) in this setting have not been determined. If bladder injury is associated with a pelvic fracture in a male patient, the possibility of a urethral injury is 5 to 29% and must be excluded.^{43,47} A successfully placed Foley catheter rules out a complete urethral disruption.

MANAGEMENT

Nonoperative

Extraperitoneal bladder injuries caused by blunt trauma are generally managed nonoperatively with 10 days of catheter drainage.^{47–49} Contraindications to nonoperative management include urinary infection; pelvic fractures requiring internal fixation; the presence of bony fragments in the bladder; bladder neck injury, which may compromise continence; rectal injury; and female genital lacerations associated with

pelvic fracture. After 10 days, plain-film or CT cystography is performed to document healing. Once the extravasation has resolved, catheter removal can be based on the patient's overall status and mobility. If extravasation persists, cystography is repeated at appropriate intervals until healing occurs.

Operative

All penetrating injuries and all intraperitoneal ruptures of the bladder are managed by means of bladder exploration and repair. If the patient requires laparotomy for associated injuries and can tolerate the extra operating time, repair of extraperitoneal bladder injuries is also recommended. Conversely, in severely unstable patients, catheter drainage can be used as a temporizing measure until the patient is able to undergo exploration.

Bladder exploration can be performed via an intraperitoneal approach or by entering the extraperitoneal space of Retzius in the anterior pelvis. Intraperitoneal injuries present as a stellate rupture of the dome of the bladder. By enlarging this opening, one can inspect the interior of the bladder to exclude concomitant extraperitoneal injuries.⁵⁰ In cases involving orthopedic reconstruction of the pelvis, the bladder may be approached extraperitoneally through the incision used to expose the pubic symphysis. Although extensive hemorrhage has been described in this scenario, it is a rare occurrence. Most extraperitoneal bladder injuries associated with pelvic fractures are anteriorly located, small in size, and easily closed without a more extensive bladder exploration.

Penetrating injuries and unrecognized blunt injuries discovered at laparotomy without previous CT cystography call for systematic evaluation. By opening the bladder vertically at the dome or along the anterior surface, one can identify sites of injury intravesically and inspect the ureteral orifices and the bladder neck. Lacerations are closed with 3-0 absorbable sutures, which approximate detrusor muscle and mucosa in one layer and provide hemostasis. In patients with penetrating injuries, entrance and exit sites must be identified. The cystotomy is then closed with two layers of continuous 2-0 slowly absorbable sutures.

Postintervention Care

Adequate urinary drainage is essential to successful healing of the repaired bladder. There is no evidence that suprapubic catheters are superior to urethral catheters in this context.^{49,51} However, the catheters placed during trauma resuscitation are not of sufficient caliber to allow easy bladder decompression; therefore, a 20 French urethral catheter should be substituted at the end of the operation. A closed-suction drain near the bladder closure (but not overlying the suture line) is recommended. Cases of severe hematuria resulting from extensive injuries or coagulopathy warrant additional drainage with a suprapubic cystostomy tube to allow irrigation of clots and proper decompression of the bladder.

The perivesical drain can be removed after 48 hours unless the creatinine level in the drained fluid indicates ongoing urinary leakage. In the majority of patients with a bladder repair, 7 days of catheter drainage is sufficient to allow healing. Because bladder repair is reliable, any complications of bladder injury are usually related to a delay in diagnosis rather than to postoperative morbidity. Azotemia, ascites, and sepsis can result from an unrecognized intraperitoneal

Figure 10 Algorithm outlining the management of bladder injury. CT = computed tomography.

Figure 11 (a) Computed tomographic (CT) cystogram showing extraperitoneal bladder rupture. A definitive discontinuity in the bladder wall is visible (arrow). (b) CT cystogram showing intraperitoneal bladder rupture.

injury. Bladder neck injury, if overlooked, leads to scarring and incompetence of the proximal sphincter mechanism, with resultant incontinence, especially in females.

Injuries to the Urethra

INITIAL EVALUATION

Almost all injuries to the male urethra [see Table 2] are caused by blunt trauma. Prostatomembranous urethral distraction injuries in males occur in 1.5% of pelvic fractures, which are the most common cause of posterior urethral injury.⁴³ Pelvic fractures with a displaced inferomedial pubic ramus and pubic symphysis diastasis have an increased risk of urethral injury. For every 1 mm increase in pubic diastasis, the risk of urethra injury increases 10%.⁵² Anterior urethral (penile and bulbar urethral) injuries are commonly caused by straddle injury but may be the result of penile fracture or penetrating injuries to the genitalia. The female urethra is rarely injured, but when such injury occurs, it is usually associated with bladder injury and pelvic fracture. Up to 40% of female urethral injuries are missed in the emergency department, emphasizing the need for a high index of suspicion in women with gross hematuria and pelvic fracture.⁵³

Blood at the urethral meatus—the classic sign of injury to the male urethra—is an indication for immediate urethrography. Attempts at catheter placement risk converting an incomplete injury to a complete disruption and are to be discouraged if urethral injury is suspected.

Because signs of urethral injury are variable, retrograde urethrography is the essential diagnostic test used for documenting the location, nature, and extent of injury. Extravasation of the contrast agent is evidence of urethral injury [see Figure 12]. In the absence of extravasation, a Foley catheter should be passed. If a catheter has been placed but its position is unclear, contrast injection will confirm its placement in the bladder. In such cases, the catheter should be left in place until a pericatheter contrast study can fully evaluate the urethra. In cases of pelvic fracture and complete

posterior urethral injury, bladder injury must be excluded by open bladder exploration or via cystography through a percutaneously placed suprapubic tube.

MANAGEMENT

Traumatic urethral injuries have traditionally been managed by means of suprapubic cystostomy, with reconstruction delayed for 3 to 6 months; however, most urethral trauma patients can undergo immediate realignment, with or without sutured repair. The exception is the patient with a straddle-type crush injury to the bulbar urethra, which should always be treated with urinary diversion and delayed repair. The recommended treatment is based on the location and mechanism of injury [see Figure 13 and Table 3].

Posterior Urethra

Posterior urethral (prostatic and membranous urethral) injuries can be managed with suprapubic cystostomy or early primary urethral realignment. Realignment without sutured repair renders definitive reconstruction unnecessary in a significant percentage of patients.⁵⁴ Bladder neck injury and wide separation of the bladder from the urethra warrant immediate surgical intervention.⁵⁵ Simultaneous rectal injury often occurs in this setting and necessitates evacuation of the pelvic hematoma, irrigation, placement of drains, and primary realignment of the urethra. Primary realignment is also preferred in cases of open reduction and internal fixation of pelvic fractures because the risk of hardware contamination is considered to be lower with a urethral catheter than with suprapubic cystostomy.⁵⁶

Primary realignment is usually performed through a lower midline abdominal incision, which allows antegrade passage of instruments through the bladder at the same time as retrograde passage of instruments from the urethral meatus. Flexible cystoscopes or magnetic-tipped catheters advanced under fluoroscopic guidance are used to place a wire into the bladder beyond the injury, and a Council-tip Foley catheter is then advanced over the wire. Neither mucosal approximation nor direct anastomosis is the goal. Suprapubic catheter

Figure 12 (a) Retrograde urethrogram of a posterior urethral injury after pelvic fracture shows extravasation at the level of the urogenital diaphragm. (b) Retrograde urethrogram of an anterior urethral injury caused by a gunshot wound shows extravasation at the level of the bulbar urethra.

Figure 13 Shown are the posterior and anterior portions of the urethra. The posterior portion comprises the prostatic urethra and the membranous urethra; the anterior portion comprises the bulbar urethra and the penile urethra. Treatment of urethral injury depends on the location and mechanism of injury.

drainage is not required, but a perivesical drain should be left in place for 48 hours.

Anterior Urethra

Immediate surgical reconstruction is preferred for penetrating injuries of the bulbar and penile urethra and for urethral injuries associated with penile fracture. For these grade III and IV injuries, primary repair is associated with a lower stricture rate than simple realignment.^{57,58} Wounds accompanied by major tissue loss and defects larger than 2 cm (e.g., grade V injuries) or major associated injuries are best treated with suprapubic tube urinary diversion (see below) and subsequent reconstruction at a tertiary referral center.

Suprapubic Cystostomy

Many centers continue to use suprapubic cystostomy as the primary management of prostatomembranous urethral disruption and straddle injuries to the bulbar urethra. Suprapubic cystostomy, with the tube percutaneously placed under fluoroscopic guidance, allows temporary urinary diversion for initial stabilization and evaluation of the patient. Cystography can then be performed via the suprapubic tube to rule out associated bladder injury. Straddle injuries must be treated with suprapubic diversion unless the urethral disruption is only partial and allows passage of a guide wire or catheter

Table 3 Management of Urethral Trauma

Location of Injury	Mechanism of Injury		
	Blunt	Penetrating	Penile Fracture
Posterior (prostatic and membranous urethra)	Realignment or suprapubic cystostomy	Realignment	—
Anterior (bulbar and penile urethra)	Suprapubic cystostomy	Surgical repair	Surgical repair

under fluoroscopic guidance. Finally, suprapubic cystostomy is also recommended for penetrating injuries to the anterior urethra if the injuries were caused by high-velocity weapons and are characterized by extensive tissue loss; if serious associated injuries are present; or if bony fractures prevent proper placement of the patient in the lithotomy position.

Female Urethra

Prompt surgical reconstruction of the bladder neck and urethra are warranted when possible. Urethral injuries distal to the external sphincter can be left unrepaired. However, proximal and midurethral injuries should be closed primarily over a catheter, with all overlying vaginal lacerations repaired concomitantly to minimize the risk of urethrovaginal fistula formation or vaginal stenosis. Placement of a suprapubic tube with delayed repair is reserved only for unstable patients.⁵³

Postintervention Care

Catheter care is of great importance after urethral reconstruction or suprapubic cystostomy. Urethral catheters should be secured to the abdominal wall in the early postoperative period. After immediate reconstruction of the anterior urethra, the Foley catheter should remain in place for 3 weeks, at which time a contrast voiding cystourethrogram should be obtained. If extravasation is present, the catheter should be replaced for 1 week and the study repeated. After primary realignment of urethral injuries, the urethral catheter is left in place for 6 weeks, at which time a pericatheter retrograde urethrogram is obtained, with the expectation that any extravasation will have resolved.

If the patients initially underwent diversion with a suprapubic tube alone, the tube should be changed after a tract has formed (usually about 4 weeks after the procedure) and then monthly until reconstruction can be performed. Stricture formation or complete obliteration of the urethra may be the final result of this nonoperative approach. Subsequent radiographic studies will indicate whether secondary endoscopic or open procedures are needed.

Injuries to the Vagina, Uterus, and Ovaries

Injuries to the female genitalia [see Table 4 and Figure 14] must be regarded as especially morbid because of their association with sexual assault and interpersonal violence, as well as because of the potential medical complications (infection and bleeding). Genital trauma is reported in 20 to 53% of sexual assault victims.^{59,60} Blunt unintentional trauma, including pelvic fracture and straddle injuries, often results in perineal and vaginal injuries and, less commonly, cervical and uterine trauma.^{61–64} Enlargement of a reproductive organ predisposes that organ to injury.^{65,66} Penetrating injuries account for almost all injuries to the fallopian tubes, the ovaries, and the nongravid uterus.⁶⁷

INITIAL EVALUATION

A history of sexual trauma must be sought; if such a history is elicited, appropriate police and support services must be notified.⁶⁸ In addition, if sexual assault has occurred, informed consent for the rest of the patient assessment must be obtained. This assessment includes a history, a physical examination, collection of evidence and laboratory specimens, and treatment, as outlined by the American College of

Obstetricians and Gynecologists.⁶⁹ The percentage of assault victims with identifiable spermatozoa in the vaginal specimens is lower than 50%.⁷⁰

All female patients with evidence of lower urinary tract and urethral injury should undergo examination of the external genitalia, as well as speculum examination of internal organs. The finding of blood implies vaginal laceration. In the presence of pelvic fracture or impalement injury, vaginal laceration warrants complete evaluation (with cystourethrography, proctoscopy, and laparotomy, as indicated) to rule out associated urinary tract and gastrointestinal tract injuries. Failure to identify vaginal injury associated with pelvic fracture may lead to abscess formation, sepsis, and death.

MANAGEMENT

Perineal lacerations in the absence of associated urinary tract and rectal injury can be managed in the emergency department. Only large hematomas must be incised and drained, with ligation of vessels. Lacerations of the vulva may be closed primarily after irrigation and débridement. Interrupted absorbable sutures allow any accumulated fluid to drain and eliminate the need for suture removal. Drains are used if there is a large cavity; if hemostasis is suboptimal, the wound may be packed.⁶⁴

Vaginal and cervical lacerations from either blunt or penetrating injury will bleed extensively if the pudendal vessels are injured.⁶⁴ If bleeding is not severe, examination and repair with local anesthesia are possible in the emergency department. If large lacerations are associated with bleeding and hematoma, speculum examination under anesthesia permits more complete assessment and repair of injuries. Vaginal lacerations should be closed with continuous or interrupted absorbable sutures that include mucosal and muscular layers. Antibiotic-soaked vaginal packing should be left in place for 24 hours. Perioperative administration of broad-spectrum antibiotics is sufficient, unless injuries are more complex.

Complex vaginal and perineal lacerations associated with pelvic fracture must be managed much more aggressively to prevent the morbidity and mortality characteristic of open fractures.⁷¹ Evaluation of vaginal injuries with the patient under anesthesia, cystography, and rigid proctoscopy are mandatory. The vaginal laceration should be closed with absorbable sutures. Even in the absence of injury to the bladder or the rectum, diversion of the urinary and fecal streams should be considered to facilitate care of the perineal wound; however, we rarely divert the fecal stream unless the perineal injury extensively involves the rectum or the sphincter.⁷² Extraperitoneal bladder rupture associated with vaginal lacerations must be repaired operatively to prevent infection of a pelvic hematoma or formation of a vesicovaginal fistula. Urologic, gynecologic, and orthopedic consultations are necessary for care of associated injuries.

Injury to the pelvic genital organs is rare in a nongravid patient. Penetrating trauma is the most common cause, and the majority of patients have associated injuries necessitating laparotomy.⁶⁶ Blunt injury of the nongravid uterus and the pelvic organs occurs in the face of preexisting abnormalities; DPL demonstrates hemoperitoneum in these instances.⁶⁷ The uterus, the organ most commonly injured, is repaired with figure-eight sutures or a two-layer closure using slowly

Table 4 AAST Organ Injury Scales for Female Reproductive Tract

Injured Structure	AAST Grade	Characteristics of Injury	AIS-90 Score
Vagina*	I	Contusion or hematoma	1
	II	Superficial laceration (mucosa only)	1
	III	Deep laceration (into fat or muscle)	2
	IV	Complex laceration (into cervix or peritoneum)	3
	V	Injury to adjacent organs (anus, rectum, urethra, bladder)	3
Vulva*	I	Contusion or hematoma	1
	II	Superficial laceration (skin only)	1
	III	Deep laceration (into fat or muscle)	2
	IV	Avulsion (skin, fat, or muscle)	3
	V	Injury to adjacent organs (anus, rectum, urethra, bladder)	3
Nongravid uterus*	I	Contusion or hematoma	2
	II	Superficial laceration (< 1 cm)	2
	III	Deep laceration (≥ 1 cm)	3
	IV	Laceration involving uterine artery	3
	V	Avulsion or devascularization	3
Fallopian tube†	I	Hematoma or contusion	2
	II	Laceration < 50% of circumference	2
	III	Laceration ≥ 50% of circumference	2
	IV	Transection	2
	V	Vascular injury or devascularized segment	2
Ovary†	I	Contusion or hematoma	1
	II	Superficial laceration (depth < 0.5 cm)	2
	III	Deep laceration (depth ≥ 0.5 cm)	3
	IV	Partial disruption of blood supply	3
	V	Avulsion or complete parenchymal destruction	3
Gravid uterus*	I	Contusion or hematoma (without placental abruption)	2
	II	Superficial laceration (< 1 cm) or partial placental abruption (< 25%)	3
	III	Deep laceration (≥ 1 cm) in second trimester or placental abruption > 25% but < 50%; deep laceration in third trimester	3; 4
	IV	Laceration involving uterine artery; deep laceration (≥ 1 cm) with > 50% placental abruption	4; 4
	V	Uterine rupture in second trimester; uterine rupture in third trimester; complete placental abruption	4; 5; 4–5

†Advance one grade for bilateral injuries, up to grade III.

absorbable sutures.⁶⁶ Avulsion of the uterine artery or extensive blast destruction of the uterus may necessitate hysterectomy.⁶⁴ When hysterectomy is necessary for trauma, the vaginal cuff should be left open to allow drainage of the operative bed.⁷³ Lacerations to the ovary or the fallopian tube are managed by primary closure or salpingo-oophorectomy if contralateral structures are normal.

After hysterectomy or repair of vaginal lacerations, a vaginal pack should remain in place for 24 hours. Hemorrhage caused by uterine injury has been treated with oxytocin,

which increases uterine tone and controls bleeding. Fertility after injury to the female reproductive organs is not well documented, but patients must be counseled about the possible adverse consequences of uterine and adnexal trauma.

Injuries to the Penis

Traumatic injuries to the penis are unusual, with variable etiology. Injury to the flaccid penis is rare, occurring mainly

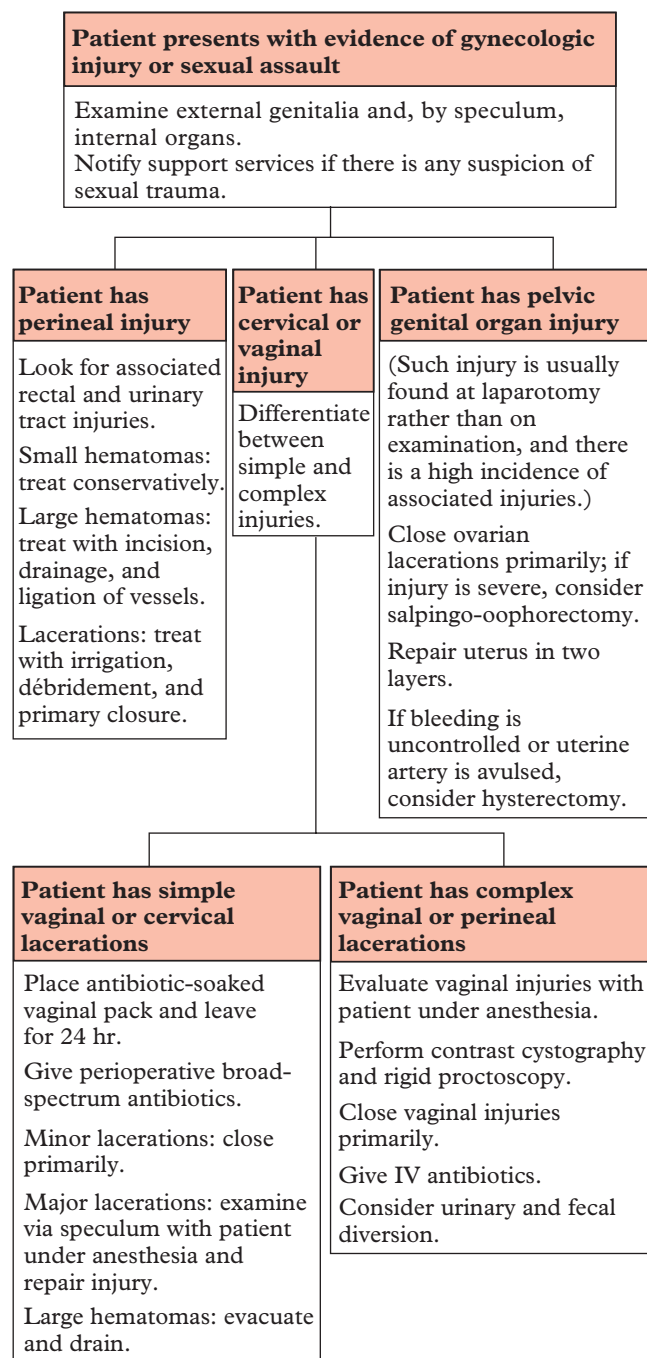

Figure 14 Algorithm outlining management of injuries to the female genitalia. IV = intravenous.

as a result of penetrating trauma and machinery accidents.^{58,74,75} However, the incidence of battlefield pelvic and genital organ injury has increased as a result of fragmentation devices and changing pattern of warfare. With the use of protective armor on the torso, 6% of contemporary genitourinary battlefield injuries affect the penis.^{76,77} Penile fracture is an uncommon injury of the tunica albuginea that occurs only with full penile rigidity, whereas penile amputation is a

devastating injury requiring immediate surgical treatment.^{78–81} Prompt operative treatment allows recovery of erectile function after most penile injuries [see Table 5]. Remarkably, in many cases, penile replantation successfully restores erectile capability.

INITIAL EVALUATION

Penile Fracture/Penetrating Injury

Missed intromission, acute bending of the penis, and a snapping or popping sound followed by acute pain and immediate detumescence are characteristic of penile fracture. Delayed presentation, attributable to embarrassment, is common. Penetrating injuries to the penis may result from deliberate attempts at mutilation, as well as from accidental firearm injury (typically occurring when a handgun goes off while in a man's pants pocket). Because of the pliability of the flaccid penis, entry and exit wounds may be complex. Penile swelling is usually limited to the shaft of the penis by the Buck fascia; scrotal and perineal ecchymosis develop if the deep investing fascia of the penis is disrupted. Imaging of the corpora cavernosa with contrast cavernosography has limited sensitivity and specificity and thus is not recommended.⁸² Associated urethral, scrotal, bladder, and rectal injuries must be excluded.

Inability to void, gross hematuria, and blood at the meatus all imply urethral injury and warrant further investigation. A uniform policy of exploration for all penile fractures and penetrating injuries will ensure that urethral injuries are identified. Passage of a catheter in the operative field with inspection of the involved urethra allows identification and primary repair of a lacerated or transected urethra.

Penile Amputation

Whether caused by a jealous lover or by self-mutilation, penile amputation is a catastrophic event.⁸³ Proper preservation of the amputated organ is critical for successful restoration of function. The amputated part should be placed on saline-soaked gauze inside a clean bag, which should then be sealed and placed inside a second bag containing ice slush.⁸¹ Cold ischemia times longer than 24 hours are acceptable and allow transport of the patient to tertiary centers, where replantation can be performed. Even at normal temperatures, replantation 16 hours after injury has been successful.⁸¹ Microsurgical repair techniques have certain advantages, including better preservation of the penile shaft skin and the possibility of a sensate glans and normal orgasmic function. However, astonishing results have also been reported with the conventional technique of corporal reattachment without microvascular reanastomosis of the dorsal neurovascular structures.

MANAGEMENT

Penile Fracture/Penetrating Injury

A circumferential subcoronal incision provides exposure after penile fracture and most penetrating injuries of the shaft and permits corporal and urethral repair. The superficial layers and skin are bluntly degloved back to the base of the penis. For deeper injuries, proximal to the suspensory ligament or in the crura, a penoscrotal or perineal incision is required to provide access to the corpus cavernosum. Rupture of the corpus cavernosum as a result of a fracture, a

Table 5 AAST Organ Injury Scales for Male Genitalia

Injured Structure	AAST Grade	Characteristics of Injury	AIS-90 Score
Scrotum	I	Contusion	1

stab wound, or a bullet wound is signaled by the presence of active bleeding and a defect in the fibrous tunica albuginea. Careful exploration and inspection of the corpus spongiosum are mandatory, even if urethrography shows no extravasation. Tunical ruptures caused by fracture are transversely oriented [see Figure 15] and sometimes extend behind the spongiosum; this structure may have to be mobilized and retracted for adequate visualization of the injury.

The tunica albuginea is closed with interrupted 3-0 slowly absorbable sutures. Débridement and curettage have occasionally been used in this setting but generally are reserved for late presentations. Skin closure is possible with most penetrating injuries to the penis. The extensive vascular supply to the skin is rarely compromised. Interrupted chromic sutures provide a cosmetic closure and allow drainage of residual blood between the sutures. A lightly compressive dressing is sufficient; tight wraps are to be avoided because they may lead to necrosis of swollen shaft skin. Catheter drainage is mandatory if urethral injury is present. Sexual intercourse is contraindicated for 1 month after penile injury.

Penile Amputation

Microsurgical replantation differs from simple corporal reattachment in that the neurovascular structures are reanastomosed in addition to the urethra and the tunica albuginea. With corporal reattachment, a spatulated end-to-end urethral anastomosis is performed with interrupted absorbable sutures over a urethral catheter. The adventitia of the corpus spongiosum is reapproximated in a second layer, and the tunica albuginea and its septum are then connected. The restored cavernosal blood flow preserves the distal corpora, the glans,

and the urethra. Ischemic skin loss is expected without reanastomosis of the dorsal artery and vein. When microsurgical techniques are available, the dorsal nerves, the dorsal arteries, and the deep dorsal vein are each reanastomosed with fine nonabsorbable sutures. Meticulous closure of the superficial tunica dartos and the skin completes the repair.

Temporary ectopic replantation of the penis has been described in cases where the perineum is heavily contaminated or too extensively damaged for immediate replantation.⁸⁴ Postoperative care includes urinary diversion, bed rest, anticoagulation (in selected cases), hydration, and monitoring of arterial flow in the distal penis.

Injuries to the Scrotum and Testes

INITIAL EVALUATION

Scrotal trauma may result in testicular injury or genital skin loss [see Table 5]. Because blunt injuries to the testicle are difficult to recognize, high-resolution ultrasonography has become a key element in the evaluation of scrotal trauma [see Figure 16]. When a straddle injury or penetrating mechanism suggests the possibility of urethral injury, retrograde urethrography is indicated.

Penetrating scrotal injuries commonly involve not only the testis but also the corpora cavernosa, the urethra, and the spermatic cord. Ultrasonography is useful to ascertain the integrity of the arterial inflow to the testis.⁸⁵ The excellent blood supply of the scrotal skin allows most penetrating injuries to be débrided and closed. Even simple bite injuries can be irrigated and closed with appropriate antibiotic coverage. Exceptions to this general rule include complex contaminated

Figure 15 Shown is a case of penile fracture. A linear tear in the tunica albuginea can be seen (arrow).

human and animal bites, which are left open and are treated with intravenous antibiotics and local wound care (or débridement in cases of severe soft tissue infection).⁸⁶

Rupture of the testicle is often immediately painful, with rapid onset of swelling. Falls, straddle injuries, and direct blows are common mechanisms of injury.⁸⁷ However, seemingly minor degrees of trauma may be associated with delayed onset of pain; in this scenario, testicular torsion must be included in the differential diagnosis. Physical signs of rupture include scrotal swelling, tenderness, and ecchymosis. Injury to the scrotal wall or the tunica vaginalis may cause significant swelling without rupture of the tunica albuginea of the testis; pelvic hematoma caused by fracture can result in massive scrotal swelling. For these reasons, blunt injury to the scrotum should be evaluated by ultrasonography unless the findings from the physical examination are normal.

The ultrasonographic characteristics of testicular rupture [see Figure 17] include loss of normal homogeneity of the testicular parenchyma, loss of continuity of the tunica albuginea, and intraparenchymal hematoma.⁸⁵ A discrete break in the tunica is relatively rare. In cases of pelvic fracture with massive scrotal edema, ultrasonography can document the integrity of the testis and allow conservative management of

Figure 16 Algorithm outlining management of injury to the scrotum or testes.

the swelling. If rupture is not documented, treatment with ice packs, analgesics, and elevation allows resolution of swelling.

MANAGEMENT

Exploration of the scrotum through a vertical incision allows inspection of the scrotal contents; when spermatic cord injury is discovered, the incision can be extended cephalad to the groin. The goal is preservation of testicular parenchyma for endocrine and cosmetic purposes; normal sperm production and transport are not expected after repair of rupture. Clots and extruded seminiferous tubules are débrided with scissors to allow closure of the tunica albuginea over the edematous parenchyma. A continuous 3-0 slowly absorbable suture is sufficient.

When spermatic cord injury is detected, the first priority is determination of the viability of the testis. A small incision into

Figure 17 (a) Ultrasonogram of ruptured testes shows intraparenchymal hematoma and heterogeneous echotexture. (b) Ultrasonogram of ruptured testes shows indistinct testicular contour and abnormal echotexture.

the tunica albuginea should cause some bleeding; if the testis is cyanotic and does not bleed when cut, orchiectomy should be performed. If only the vas deferens or spermatic vessels are injured, the testis will remain viable. Ligation of the spermatic vessels is performed in the standard fashion; if vasal ligation is necessary, use of nonabsorbable suture with long tails enables later identification for reconstruction if infertility ensues.

Scrotal skin lacerations can be closed primarily in most instances. Exceptions arise if there is a prolonged delay between injury and definitive care or if grossly contaminated wounds are associated with rectal injuries. Hemostasis should be meticulous. Interrupted suture closure of the tunica dartos and skin in separate layers, with a Penrose drain brought out through a separate dependent stab wound, limits postoperative hematoma formation. Fluffed gauze should be used for dressing, and a scrotal supporter should be used to keep the scrotum elevated. The Penrose drain is removed on postoperative day 1. There are no major restrictions to activity after scrotal surgery, and patients can be discharged once they have recovered from associated injuries.

Scrotal avulsion can be devastating and must be differentiated from complex lacerations. Skin avulsed by shear forces in MVCs may be suitable for cleansing and preparation for full- or split-thickness grafts; however, when high-speed rotating machinery is the mechanism, as when clothing and skin are caught in a power takeoff, this approach is not recommended. The intrinsic microvasculature of the skin is probably damaged. Scrotal skin loss caused by burns or electrical or mechanical injury usually spares the testis, which has a separate blood supply. Conservative débridement is possible if there is no infection, but the demarcation between viable and nonviable tissue should be identified before extensive débridement.⁸⁸ Management depends on the amount of skin remaining. Options include primary closure, immediate coverage with meshed split-thickness skin grafts, and placement of the testes in subcutaneous pouches in the thigh.

Financial Disclosures: None Reported

12 INJURIES TO THE PELVIS AND EXTREMITIES

J. C. Goslings, M.D., Ph.D., K. J. Ponsen, M.D., and O. M. van Delden, M.D., Ph.D.

Injuries to the pelvis and extremities are common, occurring in approximately 85% of patients who sustain blunt trauma. Improper management can have devastating consequences. Major long bone fractures are a sign that substantial force has been applied to the body, and they are frequently associated with torso injuries. Trauma to the pelvis or the extremities can result in injuries that are potentially life-threatening (e.g., pelvic disruption with hemorrhage, major arterial bleeding, and crush syndrome) or limb-threatening (e.g., open fractures and joint injuries, vascular injuries and traumatic amputation, compartment syndrome, and nerve injury secondary to fracture dislocation). In this chapter, we outline the basic knowledge the general or trauma surgeon requires for initial management of injuries to the pelvis, the extremities, or both.

Evaluation and Assessment

INITIAL PRIORITIES

In the surgical management of musculoskeletal injury, the priorities are (1) to save the patient's life, (2) to save the endangered limb, (3) to save the affected joints, and (4) to restore function; these priorities are pursued in accordance with advanced trauma life support (ATLS) guidelines.¹ The musculoskeletal injury that it is most important to identify during the primary survey is an unstable pelvic injury, which can lead to massive and life-threatening internal bleeding. If manual compression-distraction of the iliac crests elicits abnormal movement or pain, a pelvic fracture is probably present. In this case, a prefabricated splint or sheet wrap is applied around the pelvis to reduce the intrapelvic volume, and the legs are wrapped together to induce internal rotation of the lower limbs. Grossly deformed extremities are reduced by means of manual traction to reduce motion and to enhance the tamponade effect of the muscles. In the initial phase, control of hemorrhage from deep soft tissue lesions and vessel injury is best achieved with direct compression.

During the secondary survey, the rest of the musculoskeletal system is assessed to identify fractures, dislocations, and soft tissue injuries. It is advisable to perform a tertiary survey 24 to 48 hours after admission to detect any missed injuries, especially in multiply injured patients whose condition at admission precluded the completion of a full secondary survey.²

IMAGING

Diagnostic imaging usually begins with conventional x-rays. The pelvis is imaged during the primary survey, but x-rays of the extremities typically are obtained only after life-threatening injuries have been corrected and the patient's general condition is such that the surgeon can afford to spend the time necessary to complete extremity and spine imaging (which is often as long as several hours). Conventional x-rays of the affected limb are guided by the injury mechanism, the history, and the physical examination and

are always done in two planes (anteroposterior [AP] and lateral). Long bones should be visualized over their entire length, including the adjacent joints. After reduction of fractures and dislocations, x-rays should be repeated, unless no time is available (e.g., because of the presence of limb-threatening vascular injury).

Computed tomographic scanning is frequently used as an adjunct to conventional x-rays, especially in patients with periarticular fractures and dislocations or pelvic fractures. Axial, sagittal, coronal, and three-dimensional reconstructions allow exact determination of the extent of the fracture and the position of fracture fragments. CT scanning also helps in the process of deciding between operative and nonoperative treatment, and it facilitates preoperative planning when a surgical therapy is adopted. In addition, CT scanning may play a role in detecting bleeding sources in the pelvis, though hemodynamic instability or ongoing blood loss in the presence of a pelvic fracture usually is best managed with immediate angiography rather than CT.

Magnetic resonance imaging can be helpful with complex malunions, soft tissue injuries, and certain fracture types (e.g., scaphoid fracture).³ Bone scintigraphy and ultrasonography are less frequently employed in the setting of pelvic and extremity trauma. Triphasic bone scanning is primarily used to detect osteomyelitis, avascular necrosis, and malignant lesions, whereas ultrasonography is mostly used to assess soft tissue injuries.

CLASSIFICATION OF INJURIES

Fracture

Of the many existing fracture classification systems, the one that is most frequently used is the system developed by two Swiss organizations, the Association for Osteosynthesis (AO) and the Association for the Study of Internal Fixation (ASIF) [see Figure 1].⁴ The AO-ASIF fracture classification system serves both as a means of documenting fractures (e.g., for research purposes) and as an aid to the surgeon in assessing the severity of the fracture and determining the appropriate treatment.

In the AO-ASIF system, any given extremity fracture can be described in terms of a five-place alphanumeric designation [see Figure 1a]. The first place represents the bone injured. The second represents the segment affected by the injury (proximal, middle or diaphyseal, or distal, with malleolar a fourth category that is sometimes employed). The third represents the fracture type (A, B, or C). In middle-segment long bone fractures, type A refers to simple fractures with two fragments, type B refers to wedge fractures with contact between the main proximal and distal fragments after reduction, and type C refers to complex fractures without contact between the main fragments after reduction [see Figure 1b]. In proximal and distal long bone fractures, type A refers to extra-articular fractures with the articular surface intact, type B refers to partial articular fractures in which there is some articular involvement but part of the articular surface remains attached to the diaphysis, and type C refers to complete articular fractures in which

Figure 1 (a) Shown is the AO-ASIF classification system for fractures, as expressed in a five-place alphanumeric designation. (b) Illustrated are the three types of diaphyseal long bone fractures, along with the three groups into which each type is divided. (c) Depicted are the three types of metaphyseal or epiphyseal long bone fractures.

the articular surface is disrupted and completely separated from the diaphysis [see Figure 1c]. The fracture types are then further subdivided into three groups (1, 2, or 3), represented by the fourth place, and (mainly for scientific purposes) three subgroups (.1, .2, or .3), represented by the fifth place.

For the fracture types, groups, and subgroups, increasing letter and number values represent increasing severity, as determined by the complexity of the fracture, the difficulty of treatment, and the prognosis. Thus, an A1 fracture is the simplest injury with the best prognosis, and a C3 fracture is the most complex injury with the worst prognosis. For practical purposes, the first four places of the AO-ASIF alphanumeric designation are usually sufficient for treatment planning; the fifth (the subgroup) adds little to the process.

Pelvic ring and acetabular fractures are classified in essentially the same fashion [see Management of Pelvic and Acetabular Injuries, below].

Soft Tissue Injury

The type of soft tissue injury present and its extent are determined by the type of insult sustained (e.g., blunt, sharp, or crush), the degree and direction of the force applied, the area affected, and

the extent of contamination (if any). With closed injuries, the intact skin prevents direct assessment of the subcutaneous tissues, and as a result, soft tissue injuries are frequently underestimated. In the emergency department, a single inspection is made, and the wound is covered by a sterile dressing; at this point, it may be helpful to take pictures with a digital camera. Exact grading of the soft tissue injury is best done in the operating room by an experienced surgeon who can also decide on a treatment plan.

The system most commonly used for classification of open fractures is the one developed by Gustilo and Anderson, which divides these fractures into three types as follows [see Figure 2]^{4,5}:

1. Type I: the wound is smaller than 1 cm and results from an inside-out perforation, with little or no contamination; the fracture type is simple (type A or B).
2. Type II: the skin laceration is larger than 1 cm but is associated with little or no contusion of the surrounding tissues; there is no dead musculature, and the fracture type is moderate to severe (B or C).
3. Type III: extensive soft tissue damage has occurred, with or without severe contamination, frequently in association with compromised vascular status; the fracture is highly unstable (type C) as a result of comminution or segmental defects. Type

III fractures are further divided into the following three sub-categories:

- a. IIIA: adequate soft tissue coverage of the bone is still possible.
- b. IIIB: extensive soft tissue loss occurs with periosteal stripping and exposed bone; contamination is usually massive.
- c. IIIC: an arterial injury is present that requires repair; any open fracture accompanied by such an injury falls into this category, regardless of fracture type.

Closed fractures are less frequently classified according to the type and extent of soft tissue injury, though this does not mean that such injury is not an important consideration with closed fractures. The classification system most commonly used for closed fractures is that of Tscherne, which recognizes the following four grades:

1. Grade 0: soft tissue injury is absent or minor; the fracture type is simple.
2. Grade I: superficial abrasion or contusion is present as a result

of pressure applied by the fragment from the inside; the fracture type is simple or moderate.

3. Grade II: deep contaminated abrasions and localized skin or muscle contusion are present as a consequence of direct trauma, possibly leading to compartment syndrome; the fracture type is moderate to severe.
4. Grade III: extensive skin contusions, destruction of musculature, and subcutaneous tissue avulsion have occurred; the fracture is severe and mostly comminuted.

Timing and Planning of Intervention

In multiply injured patients, the timing of operative treatment of injuries to the pelvis and extremities depends both on the condition of the patient and on the particular combination of skeletal and soft tissue injuries sustained [see Table 1]. In such cases, the threshold for adoption of a damage-control strategy [see Damage-Control Surgery, below] to minimize operating time and tissue

Figure 2 Illustrated is the Gustilo-Anderson classification system for open fractures.

insult should be low.^{6,7} The performance of multiple definitive osteosyntheses is an option only in patients who have been successfully resuscitated (as indicated by stable hemodynamic status without a need for inotropes; absence of hypoxia, hypercapnia, and acidosis; normothermia; normal coagulation parameters; and normal diuresis).

In other cases, the timing and extent of operative treatment of musculoskeletal injuries may be more complex. Generally, if open reduction and internal fixation are indicated, the sooner the operation is performed, the better. With early operation, fracture surfaces are more easily cleaned of blood clots and other material, and reduction is facilitated by the absence of prolonged dislocation and shortening. After 6 to 8 hours, swelling develops, making both the operation and the subsequent closure more difficult and thereby increasing the risk of infection and other wound complications. There are some cases, however, in which it might be preferable to postpone a complex articular reconstruction in order to ensure that the surgical team is optimally prepared. If, for any reason, significant swelling precludes a definitive operation, it is usually safer to stabilize the fracture temporarily (e.g., with splinting or external fixation), then wait 5 to 10 days for the swelling to subside. Temporary stabilization usually allows the surgeon to achieve a

reasonable provisional reduction; however, complete joint dislocations are not acceptable. Clinically, sufficient reduction of swelling has occurred when the skin has regained its creases and is wrinkled over the operative site. Early definitive surgery may also be contraindicated when abrasion or degloving injury is present at the fracture site on admission.

Swelling is less of a problem with shaft fractures that will be treated with intramedullary nailing. If, however, it is not possible to perform nailing within 24 to 48 hours after the injury, it is better to postpone the operation for 7 to 10 days; patients operated on between days 3 and 7 are at higher risk for the acute respiratory distress syndrome (ARDS).^{8,9} If the procedure must be delayed for more than 2 to 3 weeks (e.g., because of sepsis and organ failure), reconstruction of bones and joints will be substantially more difficult. If such delay leads to suboptimal axial alignment and nonanatomic reconstruction of the articular surface, the long-term prognosis will be worse.

Thorough preoperative planning is necessary for any operation done on the musculoskeletal system. Depending on the procedure to be performed, logistical considerations may include availability of the appropriate operating team, availability of the correct operating table, availability of the specific instruments needed, avail-

ability of the appropriate implants, and availability of intraoperative imaging. Technical considerations include the operative approach to be followed and the fixation method to be used, which are determined on the basis of an understanding of the extent of the injuries and a detailed knowledge of the anatomy in the area to be exposed. For example, awkward placement of fixator pins could seriously obstruct soft tissue reconstruction if the pins are in the area that should be used for a soft tissue flap. Before operation, the correct operative site is verified (with the patient awake) and marked with a permanent marker pen. A drawing of the planned reduction maneuvers and fixation techniques may be helpful for the surgeon while also serving as an educational tool for the assisting team members. Correct documentation is important for both medical and legal reasons.

DAMAGE-CONTROL SURGERY

Immediate and complete care of all fractures, dislocations, and soft tissue injuries may seem the ideal treatment strategy for patients with musculoskeletal injuries. However, this is not always the case. Major trauma leads to a systemic inflammatory response syndrome (SIRS) characterized by increased capillary leakage, high energy consumption, and a hyperdynamic hemodynamic state. Especially in the setting of severe single-organ injury or multiple injuries, the physiologic and immunologic impact of extend-

Table 2 Goals of and Indications for Damage-Control Surgery in Management of Pelvic and Extremity Trauma

Goals	Control of hemorrhage Control of contamination Removal of dead tissue and prevention of ischemia-reperfusion injury Facilitation of ICU treatment Pain relief
Indications	Clinical parameters Multiple trauma (ISS > 15) and additional chest trauma Pelvic ring injuries with exsanguinating hemorrhage Multiple trauma with abdominal or pelvic injuries and hemorrhagic shock (BP < 90 mm Hg) Radiographic findings indicating (bilateral) lung contusion Femoral fractures in polytrauma patient Polytrauma in geriatric patient Resuscitation, operation, or both expected to last > 90 min Physiologic parameters Severe metabolic acidosis (pH < 7.20) Base deficit (< -6 mEq/L) Hypothermia (T° < 35° C) Coagulopathy (PT > 50% of normal) Multiple transfusions

ISS—Injury Severity Score PT—prothrombin time

Table 1 Time Frames for Operative Treatment of Pelvic and Extremity Trauma*

Category I: immediate	(Imminent) hemodynamic instability (e.g., pelvic fracture) Neurovascular injury with compromised vitality of extremity (Imminent) compartment syndrome
Category II: urgent (within 6–12 hr)	Open fractures (increased risk of infection) Joint dislocations that cannot be reduced in ED Primary stabilization (e.g., external fixation) in multiply injured patients who are hemodynamically stable Femoral neck fractures in patients < 65 yr (to prevent femoral head necrosis) Long bone fractures (to prevent complications and immobilization) Severe soft tissue injury (e.g., degloving caused by rollover accident) Closed fractures with compromised skin Dislocated talar neck fractures
Category III: semiurgent (within 12–24 hr)	Femoral neck, intertrochanteric, and subtrochanteric fractures Closed reduction of fractures in children Treatment of soft tissue injuries (e.g., to tendons of wrist and hand) Closed fractures that benefit from early treatment (e.g., to prevent swelling with ankle fractures) Spine fractures that are unstable or associated with neurologic deterioration Wound debridement and irrigation or washout
Category IV: semielective (within 24–72 hr or delayed)	Achilles tendon ruptures Stable spine fractures Other fractures Revision procedures other than those done for infection

*These time frames are general guidelines and may be modified in accordance with individual patient parameters (e.g., physiologic condition, soft tissue injury, and fracture type) and local preferences.

ed surgical procedures on the patient's general condition can increase the risk of the multiple organ failure syndrome (MODS), ARDS, and other complications. Balanced against this risk is the understanding that early fracture fixation in polytrauma patients is beneficial in terms of mortality and morbidity. Improved understanding of the physiologic response to major trauma over the past decade has led to the approach known as damage-control surgery (DCS) or staged surgery, the purpose of which is to keep the patient from having to deal with the "second hit" imposed by the operation right after experiencing the "first hit" imposed by the initial trauma.

Currently, DCS is widely promoted for management of intra-abdominal, vascular, and musculoskeletal injuries. It can be divided into three main phases: (1) a resuscitative phase, (2) an intensive care phase, and (3) a reconstructive phase.¹⁰ The initial focus is on control of bleeding, contamination, and temporary stabilization of fractures; time-consuming reconstructions and osteosyntheses are avoided at this point. At a later stage, when vital functions have been restored, definitive reconstructions are performed during one or more planned reoperations.

The decision whether to employ DCS should be made before the operation to avoid a scenario in which the patient's general condition of the patient deteriorates seriously during a difficult operation (e.g., a complex femoral nailing procedure) [see Table 2]. An experienced and judicious surgeon will make an appropriate decision about DCS more often than not. If, as sometimes happens despite the surgeon's best efforts, the patient's condition does show serious deterioration unexpectedly during operation, the surgeon should immediately choose a bailout option, usually involving external fixation.

As applied to musculoskeletal trauma, DCS begins with debridement of open wounds and irrigation with pulsed lavage (so-called washout). Amputation of the injured limb or limbs is considered if it appears potentially lifesaving [see Management of Life-Threatening or Limb-Threatening Injuries, Mangled Extremity, below]. During the initial debridement, osteochondral

fragments in open joint fractures are retained—provided that they are not severely contaminated—to allow later reconstruction of the joint surface. Dislocations and diaphyseal fractures are reduced and stabilized with simple external fixator frames (if necessary, placed so as to span the adjacent joint or joints), and wounds are provisionally closed. Fixator pins are placed through stab incisions in safe zones. Fractures need not be reduced anatomically under image intensifier control; the only goals at this point are to restore length and align long bone fractures and joints, to reduce contamination, and to enable postoperative wound management in the intensive care unit while definitive treatment is pending. The more complex the fixator frame, the more time-consuming its application usually is. Muscle compartments believed to be at risk for compartment syndrome are widely decompressed.

At all times, the operating surgeon must keep the goals of DCS clearly in mind. The main aim of this strategy is not necessarily a nice-looking postoperative x-ray showing parallel fixator pins and a perfectly reduced tibia; rather, it is the survival of the patient in stable physiologic condition. Depending on the severity of the injuries, the reconstructive procedures likely to be performed, and the availability of specialists or subspecialists, consultation with a plastic surgeon during the initial operation may be advisable to optimize operative and logistical planning.^{6,7}

Careful attention must be paid to the logistical aspects of DCS. As soon as the decision for DCS is made, OR personnel should be notified of the type of procedures to be performed and the implants required. It may be helpful to have a dedicated DCS equipment trolley with all the materials and equipment necessary for the first hour.¹¹ Once the patient and the operating team are in the OR, the injuries sustained, the operative plan, and the injuries (known or suspected) that need special attention (e.g., a small pneumothorax) are written down or sketched on a whiteboard so that all persons present in the OR know what is to be done.

During the operation, the surgeon should stay in close contact with the anesthesiologist regarding the condition of the patient and the procedure currently under way. If operative procedures are required in more than one organ system (e.g., laparotomy and external fixation of the femora), they should, whenever possible, be performed simultaneously by multiple teams working together. The end of the procedure should be announced well ahead of time so that the anesthesiologist can take the precautions necessary for transport of a potentially unstable patient and so that the ICU can be notified of the patient's arrival. In this way, unnecessary waiting times in the OR can be kept to a minimum.

The second phase of DCS is restoration of vital functions in the ICU. This phase is crucial for ensuring that the patient is fit to undergo a second procedure.¹⁰ Close cooperation between surgeon and critical care physician is required to outline an aggressive strategy for ventilation, circulatory support, and reversal of hypothermia, coagulopathy, acidosis, and other abnormalities. Administration of large volumes of fluid will be necessary as a consequence of massive tissue swelling and bowel edema. Cardiac monitoring with central venous access should usually be employed. Application of external fixators allows the nursing staff to place the patient in the position that is most suitable for intensive care of head, chest, and abdominal injuries, while still allowing wound inspection and dressing changes as required. During this phase, imaging studies may be performed (or, if already performed, repeated) to allow planning for repeated washouts and definitive reconstructive procedures.

The third phase in the DCS sequence is the performance of one or more planned reoperations. This usually takes place at least 24

to 48 hours after the initial procedure, when the patient is stable and normothermic and has normal or near-normal coagulation parameters.¹⁰ Subsequent visits to the OR are used to continue wound debridement and coverage and to exchange external fixators for definitive fixation (e.g., with intramedullary nails).^{12,13} During these operations, multiple teams can work simultaneously on the repair of abdominal, musculoskeletal, and other injuries. The period from postinjury day 5 to day 10 is often referred to as the window of opportunity for reconstruction of intra-articular or periarticular fractures and of upper-limb fractures.

Management of Life-Threatening or Limb-Threatening Injuries

LIFE-THREATENING PELVIC TRAUMA

Pelvic fractures are frequently associated with significant hemorrhage, not only because of the fracture itself but also because pelvic trauma is often accompanied by serious injuries to other parts of the body (e.g., the chest or the abdomen). Significant arterial hemorrhage is present in approximately 25% of patients with unstable pelvic fractures.^{4,5,10,14,15} Bleeding from pelvic trauma can be quite severe: as much as 4 L of blood may accumulate in the retroperitoneal space. Whether hemorrhagic shock is associated with certain fracture types remains a matter of debate, but there is certainly a link between the severity of the pelvic injury and the incidence of hemorrhagic shock. Hemorrhagic shock in patients with pelvic fracture strongly influences outcome and necessitates immediate evaluation and treatment.

Hemorrhage may originate either from within the fractured pelvic bones themselves or from torn arteries and veins in the pelvis, which are in close proximity to the bony structures of the pelvis. In particular, the presacral venous plexus and the internal iliac arteries and side branches may be lacerated. The most commonly injured anterior branches of the internal iliac artery are the internal pudendal artery and the obturator artery, whereas the most commonly injured posterior branches are the superior gluteal artery and the lateral sacral artery.^{16,17}

Given that bleeding in pelvic fracture patients can occur in other body compartments besides the pelvis and can be arterial as well as venous, it is of the utmost importance to identify its source and, ideally, determine its nature as soon as possible. This information is crucial in determining what the next steps in management should be [see Figure 3].

The first step after diagnosing a pelvic fracture should be the immediate application of some type of external stabilization device (e.g., a sheet wrap or a device such as the Pelvic Binder [Pelvic Binder Inc., Dallas, Texas]) [see Figure 4].¹⁸ The rationale behind this step is that approximating the fractured bones and thereby decreasing the volume of the pelvis may reduce blood loss, particularly from the fractured bones and the lacerated venous plexus. In addition, stabilization may minimize further damage to blood vessels and prevent dislodgment of recent clots. It is doubtful, however, whether this procedure actually reduces arterial hemorrhage to a significant degree.

In hemodynamically unstable patients with clinical signs of a pelvic fracture, the next step (immediately after—or, preferably, while—x-rays of the chest, the pelvis, and the cervical spine are obtained according to ATLS protocols) should be the FAST (focused assessment for sonographic evaluation of the trauma patient) to rule out a significant intra-abdominal bleeding source. If the FAST is negative and no other obvious sources of hemorrhage (e.g., chest or extremities) are found, the pelvis is the most

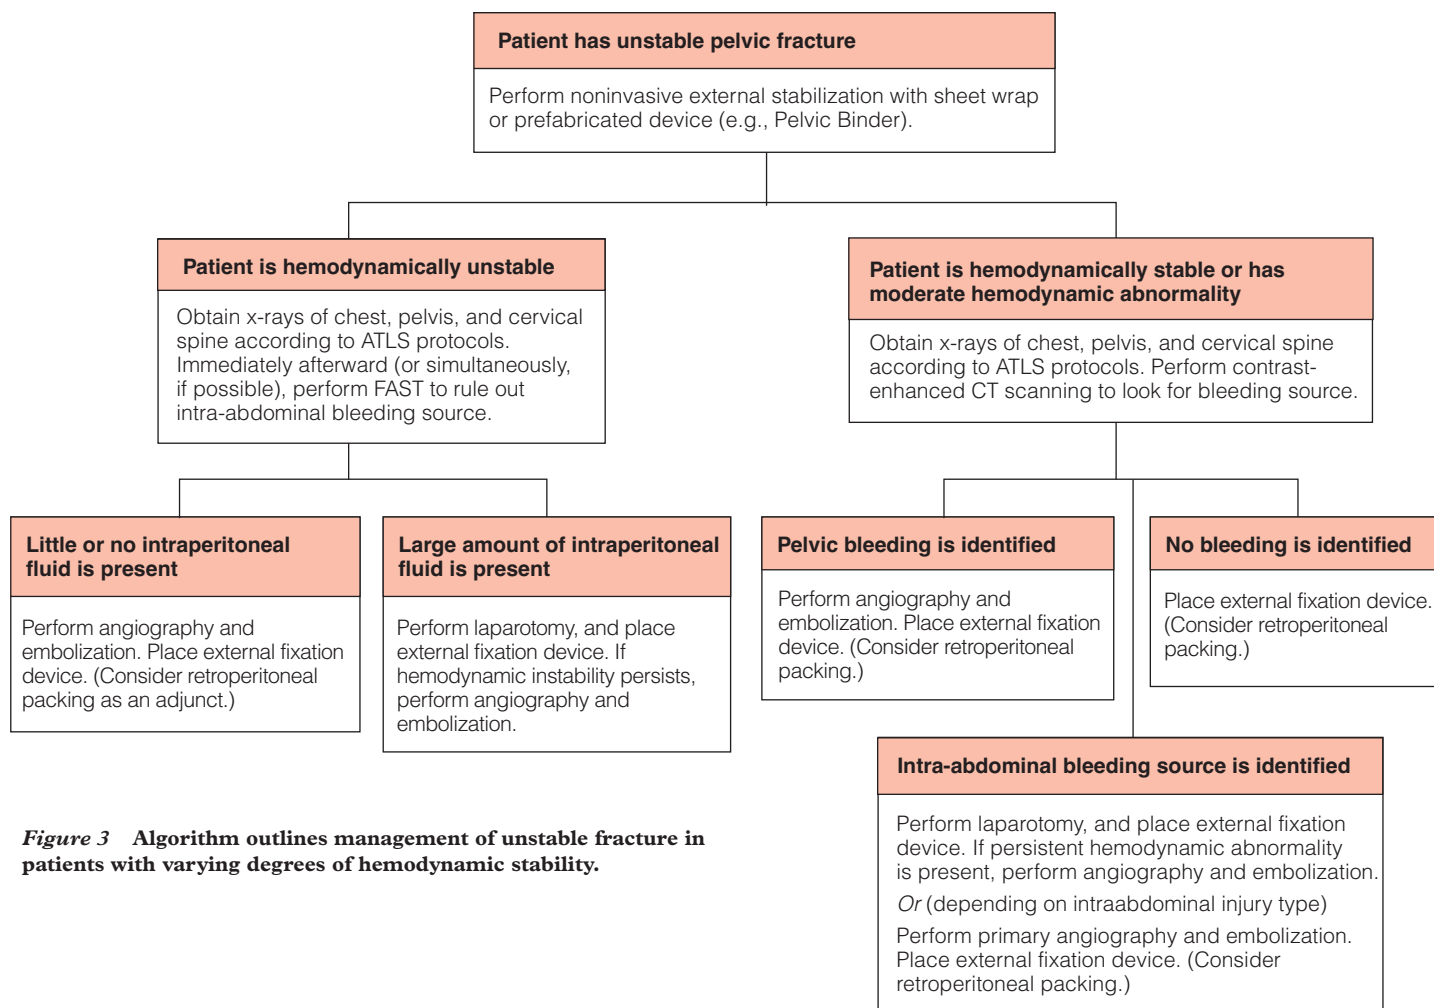

Figure 3 Algorithm outlines management of unstable fracture in patients with varying degrees of hemodynamic stability.

likely source of the bleeding. The question then arises whether the pelvic hemorrhage is predominantly arterial or venous. An arterial bleeding source in the pelvis is found in 73% of hypotensive patients who do not respond to initial fluid resuscitation.¹⁹

Contrast-enhanced CT scanning is extremely helpful in determining the presence of arterial hemorrhage in cases of pelvic fracture, but it can be performed only if the patient is stable enough to undergo the time-consuming transfer to the imaging suite. If a CT scanner is available in the shock room, it may be possible to extend the use of this modality to unstable patients. Extravasation of contrast medium, a large retroperitoneal hematoma, or abrupt cutoff of an artery on CT indicates that angiographic embolization is necessary. Contrast extravasation (so-called contrast blush) is a particularly good predictor of arterial hemorrhage necessitating embolization, having a sensitivity and specificity of well over 80%.²⁰ Thus, CT is an ideal means of identifying patients who should be treated with angiographic embolization and ideally should be performed in all pelvic fracture patients who are stable enough to undergo this procedure.

Arterial hemorrhage should preferably be treated by angiographic embolization, which has shown excellent results in current studies [see Table 3].^{21,22} Several authors have argued that in unstable patients, angiographic embolization should be done immediately, before operative placement of an external fixation device, because the chance of finding an arterial bleeding source is high and because the duration of the interval between arrival in the ED

and the performance of embolization strongly influences outcome. Angiographic embolization with gel foam or coils can almost always be performed via the common femoral artery approach, even with a sheet wrap or an external fixation device in place. Success rates exceed 90%, and major complication rates are below 5%. This technique does, however, require a skilled, experienced, and permanently available interventional radiology service.

In patients with unstable fractures, venous hemorrhage is treated with operative placement of an external fixation device. This measure requires specific expertise on the part of the trauma surgeon; in experienced hands, it should take no longer than 20 minutes to perform. Patients with more severe pelvic fractures (e.g., AO-Tile type B and C fractures and higher grades of lateral compression and anteroposterior compression fractures [see Management of Pelvic and Acetabular Injuries, Pelvic Ring, below]) probably benefit most from this procedure. Retroperitoneal packing may be employed as an adjunct to external fixator placement.²³ It is unlikely that external fixation has a significant impact on arterial hemorrhage; consequently, it is vital to decide whether angiographic embolization should precede placement of an external fixation device in the OR.

The optimal strategy for controlling bleeding in patients with life-threatening pelvic injuries remains subject to debate.^{24,25} We favor a prominent role for CT scanning and angiographic embolization, whereas others favor more liberal use of surgical retroperitoneal packing of the pelvis.

Figure 4 (a) Shown is initial stabilization of pelvic fracture in a patient with severe head injury, life-threatening unstable pelvic fracture, distal femoral fracture, and proximal tibial fracture. (b) Shown is the same patient after DCS.

OPEN FRACTURES AND SOFT TISSUE RECONSTRUCTION

Approximately 3% to 5% of all fractures and 10% to 15% of all long bone fractures are open. The prognosis after an open fracture is very different from that after a closed fracture; treatment of open fractures is much more complex than treatment of simple fractures or traumatic wounds. The existence of an open fracture means that a great deal of energy has been delivered to the bone to produce soft tissue disruption. Accordingly, it can be inferred that there has been considerable stripping of muscle, periosteum, and ligament from the bone, resulting in relative devascularization, and that varying degrees of contusion, crushing, and devascularization of the associated soft tissues have occurred. All of these events greatly influence the rate of healing, the incidence of nonunion, and the risk of infection (most commonly by *Staphylococcus aureus*, *Enterococcus*, or *Pseudomonas*). As noted [see Evaluation and Assessment, Classification of Injuries, Fracture, above], open fractures are typically classified according to the system formulated by Gustilo and Anderson.^{4,5,26}

Management of open fractures in the ED starts with a detailed history that includes the patient's medical condition before the injury, the mechanism of injury, and the time elapsed since the injury. A careful physical examination is then performed, with particular attention paid to neurovascular status, muscle function, and the presence or absence of associated injuries. Compartment syndrome [see Management of Life-Threatening or Limb-Threatening Injuries, Mangled Extremity, below, and 7:13 Injuries to the Peripheral Blood Vessels] should be ruled out in patients at risk; as many as 10% of open tibial fractures are associated with compartment syndrome as a result of severe soft tissue injury. If the limb is malaligned, gentle gross reduction should be performed to relieve any vascular compromise. The wound is then inspected, and a sterile dressing is applied. Once this is done, the dressing should not be removed until the patient is in the OR and preparation for operation has begun. The need for repeated inspections by various specialists can be eliminated by taking pictures of the fractured limb with a digital camera. A temporary splint is applied to the limb to relieve pain and prevent further soft tissue injury. X-rays are obtained in two planes, with the adjacent joints included. Antibiotic treatment is started in the ED, and antitetanus measures

are instituted according to local protocols.

The goals of treatment are to prevent infection, achieve adequate soft tissue coverage, allow bone healing, and promote early and full functional recovery. The basic principles of management consist of aggressive debridement, open wound treatment, soft tissue and bone stabilization, and systemic administration of antibiotics.^{4,5} These principles have reduced the formerly high mortality associated with open fractures to acceptable levels.

High-velocity gunshot wounds and open fractures must be approached differently from closed fractures because of the force imparted to the soft tissues. Open fractures call for emergency surgical treatment. Ideally, such treatment should begin within 6 hours of injury; the incidence of infection is directly related to the time elapsed before initiation of treatment. Typically, a second-generation cephalosporin is administered for 48 to 72 hours; prolonged administration is not necessary. For grade III open fractures, gentamicin should be added to cover gram-negative bacteria; for farmyard injuries, which are at risk for contamination with *Clostridium*, penicillin should be added.^{27,28}

The first stage of operative treatment consists of thorough irrigation of the wound with 6 L of normal saline; pulsed or jet lavage

Table 3 Indications for Angiographic Embolization in Patients with Pelvic Fracture

Hemodynamic instability; FAST negative for intra-abdominal bleeding source; inadequate response to fluid resuscitation
Contrast blush on contrast-enhanced pelvic CT scan
Large retroperitoneal hematoma on CT scan; expanding retroperitoneal hematoma on sequential CT scans
Persistent hemodynamic instability after operative placement of external fixator, laparotomy, or both
Hemodynamic stability with prolonged transfusion requirement (> 3 units of RBCs/24 hr) or other clinical signs of ongoing hemorrhage

FAST—focused assessment for sonographic evaluation of the trauma patient
RBCs—red blood cells

can be helpful for this purpose. Cultures are ordered at this time. To determine the true extent of the soft tissue damage, it is frequently necessary to enlarge the skin wound. Foreign contaminants, as well as dead bone and other devitalized tissues, predispose to infection and should therefore be removed. It is good practice to perform a routine second-look operation 48 to 72 hours after the initial debridement; debridement should be repeated until the soft tissues appear healthy and clean.

Although grade I open fractures may sometimes be treated in much the same way as similar closed fractures, grade II and grade III open fractures must be surgically stabilized during the second stage of the initial operation. Restoring of the normal anatomy through reduction and stabilization improves circulation; promotes healing of bone and soft tissue; reduces inflammation, bleeding, and dead space; and increases revascularization of devitalized tissue. It also results in earlier mobilization of multiply injured trauma patients and improves their overall status.

Internal fixation is preferred for most open fractures, with plates and screws mostly used for articular and metaphyseal fractures and intramedullary nailing for femoral and tibial shaft fractures. It is not always necessary, however, to achieve definitive fixation in the first operation. In the case of complex fractures for which additional imaging or a specialized operative team is required, a correctly placed external fixator is a safe and sensible option. External fixation as a temporary bridge to definitive fixation is also frequently used for severely contaminated grade III open fractures. Surgically created wound extensions may be closed; however, the traumatic wound itself should be left wide open. If the wound is small, a portion of the surgical extension should be left open to allow adequate drainage and to prevent the traumatic wound from sealing off prematurely. Every attempt should be made to cover bone, joint surfaces, implants, and sensitive structures (e.g., tendons, nerves, and blood vessels) with available local soft tissue, but such coverage must be achieved without tension. As an alternative to soft tissue coverage, a temporary method of wound coverage may be chosen (e.g., traditional wet dressings, synthetic membranes, allografts, or other skin substitutes).^{4,5,29,30}

Because leaving a wound open for prolonged periods increases the risk of infection, skin coverage and soft tissue reconstruction should ideally be achieved within 1 week after the injury. In the case of a grade I or II open fracture for which the initial culture is negative, the wound may be allowed to close by granulation and secondary intention, or the patient may be returned to the OR in 5 to 7 days for delayed primary closure. For larger wounds, split-thickness skin grafts are often required. For grade III open fractures, some type of flap is often required for soft tissue coverage [see 3:7 *Surface Reconstruction Procedures*]. Local fasciocutaneous flaps are suitable for smaller defects with intact surrounding skin. Muscle flaps have the advantage of adding vitality to exposed bone and can cover substantial defects; they are frequently covered with a split skin graft. Large wounds and those for which a local flap is not suitable require a free flap that is anastomosed to the local vessels. The flap procedure should preferably be done early, 5 to 10 days after the injury; some authors have even reported good results with definitive soft tissue reconstruction completed during the initial operation (so-called fix and flap).^{4,5,31}

A comparatively new method of wound coverage is negative-pressure wound therapy (NPWT) with a vacuum-assisted closure device (VAC Abdominal Dressing System; Kinetic Concepts, Inc., San Antonio, Texas).^{32,33} The perceived advantages of this approach include provision of a moist wound healing environment, reduction of the wound volume, minimization of bacterial colonization, removal of excess fluid, and (most important) pro-

motion of granulation tissue. Sponges are available in different sizes and can be further trimmed to fit the size of the wound, filling all dead space. An airtight seal is created with an adhesive drape covering the wound and the sponge. Dressings are changed every 2 to 4 days until the desired goals are reached. NPWT has proved to be a viable adjunct for treatment of various soft tissue injuries, including open tibial fractures and pelvic injuries). It is also a useful means of securing skin grafts and is reported to lead to improved graft survival. Although NPWT has yielded promising results in several case series, it should still be regarded primarily as a method of providing temporary coverage of soft tissue defects, not as a replacement for surgical debridement. Surgeons using NPWT should take care not to delay definitive closure, even if such closure involves a complex free muscle transfer.

Rehabilitation should be started soon after the operation. It is facilitated by following an aggressive treatment algorithm consisting of adequate fracture stabilization and early soft tissue coverage to prevent prolonged immobilization of joints and soft tissues. Infection is the most common complication after an open fracture and can be the result of inadequate surgical technique, incomplete debridement, or delayed soft tissue coverage. Open fractures are also associated with a higher incidence of delayed union and nonunion, which often necessitate placement of a cancellous bone graft or, in the case of a large defect, a free fibular graft.

MANGLED EXTREMITY

One of the more difficult decisions for a trauma surgeon is whether to amputate a severely injured or mangled extremity [see 7:13 *Injuries to the Peripheral Blood Vessels*]. The Mangled Extremity Severity Score (MESS) is frequently used as an aid in making this decision,^{4,5} with a score of 7 or higher generally considered an indication for amputation. The final decision whether to amputate or to attempt salvage, however, is based on the individual patient's overall condition, level of neurovascular function, and expected functional result.^{34,35}

The decision between amputation and salvage does not necessarily have to be made immediately; often, it can wait until the involved specialists have discussed the matter in the hours or days following the initial operation. If a mangled extremity does not pose an acute threat to the patient during the initial resuscitation, it may be best treated with irrigation and debridement (as with open fractures), some form of external stabilization, and temporary soft tissue coverage. Amputation in the acute phase should be performed at a safe level by means of a guillotine technique, combined with open wound management.

The functional prognosis after limb salvage is based on the presence or absence of nerve injury and the surgeons' judgment of whether adequate vascularization, soft tissue coverage and long-term bony stabilization are likely to be achievable. Often, multiple operations must be performed over several months, and even then, the outcome may be uncertain. In patients with limbs at high risk for amputation, the 2-year outcomes after reconstruction typically are about the same as those after amputation.³⁶ Accordingly, some patients may be better served by early amputation as definitive treatment.

COMPARTMENT SYNDROME

Compartment syndrome is defined as high-pressure swelling within a fascial compartment [see 7:13 *Injuries to the Peripheral Blood Vessels*]. Many physicians still believe, incorrectly, that compartment syndrome cannot develop in conjunction with an open fracture, because the break in the skin provides decompression. This is a dangerous assumption: compartment syndrome occurs in

Figure 5 Algorithm outlines diagnosis of suspected compartment syndrome.

a significant number of patients with open fractures—for example, as many as 10% of patients with open tibial fractures. The most common cause of compartment syndrome is hemorrhage and edema in the damaged soft tissues seen with fractures. Other causes include a too-tight dressing or cast, disruption of the limb's venous drainage, advanced ischemia, and eschar from a circumferential burn. Multiply injured patients with hypovolemia and hypoxia are predisposed to compartment syndrome.^{4,5,10}

The key to diagnosis of compartment syndrome [see Figure 5] is to maintain a high level of suspicion in any situation involving an extremity injury where there is a significant chance that this syndrome might develop (e.g., tibial fractures, forearm fractures, and all comminuted fractures associated with severe soft tissue injury). The diagnosis is primarily a clinical one, with the five Ps—pain, pallor, paresthesia, paralysis, and pulselessness—constituting the classic signs. The surgeon should not wait until all these signs are present; the prognosis is much better if they are not. Severe ischemic muscle pain occurs that is unrelieved by the expected amounts of analgesia. On palpation, the compartment is tense and swollen, and passive stretching of the digits of the extremity

increases the pain. Paresthesia occurs early and should be actively watched for; paralysis develops when ischemia has caused permanent damage. Pulselessness occurs late and is a relatively rare sign; it has been shown that irreversible damage can occur in a patient who still has palpable pulses.^{4,5,10,37}

Measurement of compartment pressures is also employed in the diagnosis of compartment syndrome. Monitoring can be particularly helpful in patients who are not alert or are difficult to examine.³⁸ There is no agreement on what constitutes the critical pressure threshold for a definitive diagnosis. An absolute value of 30 to 35 mm Hg has frequently been adopted as a diagnostic indicator; however, the evidence suggests that the difference between the diastolic arterial pressure and the pressure in the involved compartment (delta pressure, or Δp) is more important than any particular absolute value. Currently, a diagnosis of compartment syndrome is usually made if Δp is less than 30 mm Hg, depending on the clinical signs and the level of suspicion.

If compartment syndrome is suspected, the first step is to remove all circumferential bandages to relieve any pressure. If a plaster cast is present, it should be split, spread, or removed; if necessary, maintenance of reduction should be sacrificed. If the clinical picture does not improve after these measures are taken, then a decompressive fasciotomy is indicated. Fasciotomy is described in greater detail elsewhere [see 7:13 *Injuries to the Peripheral Blood Vessels*].

PERIPHERAL VASCULAR INJURY

Vascular injuries can result from either blunt or penetrating trauma to the extremities, though the vascular injuries seen in urban trauma centers tend to be caused more often by penetrating trauma. Early diagnosis and prompt multidisciplinary treatment are crucial for successful management. The severity of the vascular injury and the length of the interval between injury and restoration of perfusion are the major determinants of outcome.^{37,39–42} Diagnosis and management of such injuries are outlined in greater detail elsewhere [see 7:13 *Injuries to the Peripheral Blood Vessels*].

There has been considerable discussion regarding the optimal order of repair in cases of combined musculoskeletal and vascular trauma—that is, whether fracture stabilization should precede vascular repair or follow it.⁴³ Fracture stabilization facilitates the exposure needed for vascular repair and reduces the risk of subsequent disruption of a fresh arterial repair, but it inevitably takes time to perform. Rapid application of an external fixator is a good alternative for extensive fracture repairs. Insertion of a temporary intraluminal shunt can be valuable and limb-saving when DCS is performed in a patient with severe vascular extremity injury or when a patient has a grossly unstable fracture that must be stabilized before arterial repair is possible.⁴⁴ Endovascular repair plays a limited, albeit growing, role in the treatment of arterial injuries associated with extremity trauma.⁴⁵

PERIPHERAL NERVE INJURY

Injury to a peripheral nerve can result in loss of motor function, sensory function, or both; it is the principal factor accounting for limb loss and permanent disability. Because the upper extremities have less muscle and bone mass and more neurologic structures than the lower extremities do, upper-extremity injuries are twice as likely to result in nerve damage as lower-extremity injuries are. Penetrating injuries from cuts or stab wounds that result in a clean laceration of a nerve are amenable to early intervention and repair; penetrating injuries from gunshot wounds are more difficult to assess and manage. Blunt

injuries result primarily from compression or stretching.^{4,5,46-48}

Nerve injuries are generally categorized according to the Seddon classification system, which divides them into three types: (1) neurapraxia, (2) axonotmesis, and (3) neurotmesis. Complete recovery from neurapraxia and axonotmesis can usually be achieved, but neurotmesis usually necessitates surgical intervention. How quickly and successfully nerves regenerate depends on several factors, including age, type of nerve (sensory or motor), level of injury, and duration of innervation.

Careful assessment of motor and sensory function is essential for diagnosis. Additional diagnostic information can be obtained by means of electromyography (EMG), MRI, and nerve conduction studies.

In the setting of blunt trauma, surgical treatment is recommended for closed injuries when the injured nerve shows no evidence of recovery either clinically or on electrodiagnostic studies done 3 months after the injury. It is also recommended for gunshot wounds without vascular or bony problems; such wounds have relatively good potential for neurologic recovery. For most open injuries (e.g., laceration with neurotmesis), surgical exploration at the earliest opportunity is recommended. If possible, the nerve is reapproximated primarily and the epineurium is sutured, or (sural) nerve grafts are employed.^{4,5,46}

Physical therapy should be started soon after nerve injury to maintain passive range of motion in the affected joints and preserve muscle strength in the unaffected muscles. Splinting of affected joints may be necessary to prevent contractures and minimize deformities.

CRUSH SYNDROME

Crush syndrome (also referred to as traumatic rhabdomyolysis) is a clinical syndrome consisting of rhabdomyolysis, myoglobinuria, and subsequent renal failure. It is caused by prolonged compression of muscle tissue (frequently in the thigh or the calf) and is usually seen in victims of motor vehicle accidents who required a long extrication procedure or in earthquake victims who are rescued from beneath rubble after being trapped for several hours or days. Once released from entrapment, crush syndrome patients are likely to exhibit agitation, severe pain, muscle malfunction, swelling, and other systemic symptoms.^{4,5,10,49,50}

The pathophysiologic process underlying this syndrome begins with muscle breakdown from direct pressure, impaired muscle perfusion leading to ischemia and necrosis, and the release of myoglobin. As long as the patient is entrapped, the ischemic muscle is isolated from the circulation, and this isolation affords some protection against the systemic effects of the released myoglobin and other toxic materials. Extrication and the resulting reperfusion of necrotic and ischemic muscle lead to the second insult, the reperfusion injury. This injury is caused by the formation of toxic reactive oxygen metabolites, which leads to failure of ion pumps and increasing permeability of cell membranes and microvasculature. When large amounts of muscle are involved, the resulting fluid changes can rapidly induce shock. The large quantities of potassium, lactic acid, and myoglobin that are released into the circulation can lead to renal failure, disseminated intravascular coagulation, and circulatory arrest.^{49,50}

Treatment should begin at the time of extrication so as to anticipate the onset of the syndrome. The first step is initiation of I.V. fluid therapy, starting with a 2 L crystalloid bolus and continuing with crystalloid infusion at a level of 500 ml/hr (the dosage must be adjusted in pediatric and cardiac patients). Cardiac monitoring is essential (T waves indicate hyperkalemia). Intravascular fluid expansion and osmotic diuresis, by maintaining high tubular vol-

ume and urine flow, may prevent renal failure. Forced diuresis can be achieved by giving mannitol or other diuretics. Alkalization of the urine with sodium bicarbonate (1 mEq/kg I.V. to a total of 100 mEq) is a controversial measure but is recommended by some on the grounds that it should, in theory, reduce intratubular precipitation of myoglobin. If compartment syndrome is suspected, compartment pressures should be measured [see Compartment Syndrome, *above*].^{49,50}

General Management of Fractures

FIXATION METHODS AND IMPLANT TYPES

Fracture fixation can be accomplished either nonoperatively (by means of external splinting) or surgically. Surgical fixation can be achieved with many different techniques, which yield varying degrees of stability. Screws, metal wires (e.g., Kirschner or cerclage wires), plates, nails, and external fixators have all been used for this purpose. Surgical fixation methods may be broadly divided into techniques of absolute stability and techniques of relative stability.⁴

Treatment of fractures with techniques of absolute stability was widely promoted by the ASIF. Anatomic reduction and achievement of absolute stability by means of interfragmentary compression plating were advised for treatment of articular, metaphyseal, and diaphyseal fractures. This method reduces strain at the fracture site and allows bone healing without visible callus formation (so-called direct bone healing). However, obtaining interfragmentary compression usually necessitates a fairly extensive surgical approach, which disturbs the local blood supply.

Unlike techniques of absolute stability, techniques of relative stability (e.g., intramedullary nailing, use of bridging plates across a comminuted fracture, and external fixation) allow small interfragmentary movements to occur when a load is applied across the fracture site. Such movements can stimulate callus formation and lead to union of the bone in four stages: (1) inflammation, (2) soft callus, (3) hard callus, and (4) remodeling. The various techniques of relative stability (also referred to as splinting or bridging techniques) yield varying degrees of stiffness.

Both biologic factors (fracture healing) and biomechanical factors (strength and stiffness) are important for recovery after a fracture. Over the past two decades, clinical experience and data from basic studies have led to a shift in focus away from the mechanical aspects of fracture treatment and toward the biological aspects. Today, a common practice is so-called biologic osteosynthesis, which means careful handling of the soft tissues to take advantage of the remaining biologic support, coupled with the use of techniques of relative stability to stimulate callus formation. Anatomic reduction is no longer considered a goal in itself, except in the case of intra-articular fractures.⁴

Conventional dynamic compression plates are applied tightly against the bone. Their application can compromise the blood supply and thereby induce partial necrosis of the underlying bone. The presence of avascular tissues may reduce the healing potential and lower the local resistance to infection. To overcome some of these disadvantages, plates with smaller contact areas were developed. This process has culminated in the introduction of locking compression plates (e.g., LCP; Synthes, West Chester, Pennsylvania), which can be regarded as noncontact plates. The LCP is a plate-and-screw system in which the screws are also locked in the plate by means of an extra thread in the head of the screw; thus, the plate is no longer tightly fixed to the bone and the periosteum. Locking compression plates (also referred to as locked internal fixators) are designed in such a way that both conventional dynamic compres-

sion techniques and bridging techniques can be used, depending on the fracture type. They may be applied via a less invasive approach using closed reduction techniques.^{4,5}

Intramedullary nails are placed within the medullary canal and therefore have the same biomechanical properties in both the frontal and the sagittal plane. They differ from plates in that the latter are attached eccentrically to the bone. Intramedullary nails may be inserted in either an unreamed or a reamed fashion; both techniques have advantages and disadvantages. With unreamed nailing, the nails are inserted without widening the medullary canal. This approach causes somewhat less operative trauma than reamed nailing, but it places some limitations on the diameter and strength of the nail and the locking bolts. If larger-diameter nails (> 9 mm) are needed, the medullary canal must be reamed to accommodate them. Reaming takes time, leads to increased intramedullary pressure, and produces debris that may be embolized in the pulmonary circulation. The clinical consequences of reamed intramedullary nailing have not yet been fully clarified. Current evidence suggests, however, that reamed nailing is associated with significantly lower rates of nonunion and implant failure than unreamed nailing is.^{4,5,51}

External fixators consist of metal pins (Schanz screws) that are placed in the bone proximal and distal to the fracture and connected outside the skin by one or more rods. Most external fixators are used only on one side of the limb, but in specific instances, multiplanar or circular devices may be used. The stability of the frame depends primarily on the stiffness of the rods, the distance between the rod or rods and the bone (the smaller the distance, the greater the rigidity), and the number, placement, and diameter of the fixator pins. As a general rule, two pins proximal and distal to the fracture are sufficient for fixation of long bone fractures. The main advantage of external fixators is that their use minimizes additional surgical trauma. The main disadvantages are the occurrence of pin-tract infections and the frequent lack of stability for definitive fracture treatment. Appropriate placement of fixator pins requires a detailed knowledge of the cross-sectional anatomy of the injured limb.^{4,5}

BASIC PRINCIPLES OF TREATMENT

Although most fractures heal readily with casting, long periods of immobilization with restriction of muscle activity, joint motion, and weight bearing are known to lead to so-called fracture disease, characterized by muscle atrophy, joint stiffness, disuse osteoporosis, and persistent edema. Accordingly, the goals of fracture treatment should include not only the achievement of bony union but also the early restoration of muscle function, joint mobility, and weight bearing.^{4,5}

Currently, there are seven main indications for operative treatment of fractures:

1. Preservation of life (e.g., decreasing morbidity and mortality through fixation of femoral shaft fractures);
2. Preservation of a limb (as with open fractures, fractures associated with vascular injury, and fractures complicated by compartment syndrome);
3. Articular incongruity;
4. Facilitation of early mobilization and rehabilitation;
5. Inability to maintain reduction with conservative treatment;
6. The presence of more than one fracture in the same limb (so-called floating joint); and
7. The presence of additional fractures in other limbs (e.g., bilateral humeral or tibial fractures).

Improved understanding of the biology of fracture repair and

the importance of the soft tissues has led to substantial changes in the treatment of diaphyseal fractures. It is now widely recognized that anatomic reduction of each fracture fragment is not always a prerequisite for restoration of normal limb function (see above). For most long bone fractures, radial and ulnar fractures excepted, the most important goal is restoration of the mechanical axis of the limb without significant shortening, angulation, or rotational deformity. Good functional results may be expected even if fracture fragments lying between the proximal and distal main fragments are not anatomically reduced.^{4,5}

In the upper extremity, both plates and intramedullary implants are frequently used for operative fixation of fractures. In the lower extremity, intramedullary nails are generally preferred because they allow early weight bearing, in contrast to plates and screws, which are more susceptible to failure. However, intramedullary nailing may not be suitable for shaft fractures that extend into the metaphysis or the adjacent joint. The treatment plan may also be influenced by the local condition of the soft tissues (e.g., the presence or absence of contusions or wounds), the quality of the bone (e.g., the presence or absence of osteoporosis), and the origin of the fracture (pathologic or nonpathologic).^{4,5}

For intra-articular fractures, alignment alone is insufficient. Anatomic reduction of the articular surface is required to restore joint congruity, and rigid fixation is necessary to allow early motion and thereby prevent the joint stiffness resulting from prolonged immobilization. Impacted osteochondral fragments are elevated, and the resulting metaphyseal defect underneath is filled with cancellous bone or a bone substitute. Fracture fragments may be reduced either via direct exposure or via more limited approaches, with the assistance of an image intensifier or arthroscope, or both. Regardless of which approach is followed, care must be taken not to devascularize bone fragments. Fixation may be achieved with metal wires, screws, and plates. The reconstructed articular surface is connected to the diaphysis with plates or, alternatively, external fixators.^{4,5}

Nonoperative treatment usually consists of application of casters or (less frequently) traction and may be employed as either temporary or definitive therapy. It reduces the risk of infection and eliminates operative risk, but it also frequently results in a longer time to union, a higher risk of malunion, and a greater likelihood of stiffness of the involved joints. Accordingly, nonoperative management is mostly reserved for extra-articular and minimally displaced fractures.^{4,5}

Autologous bone grafting remains the gold standard for improving and accelerating fracture healing. In recent years, however, various other methods have been developed and evaluated for this purpose. There is some evidence from randomized trials indicating that low-intensity pulsed ultrasonography may shorten the healing time for fractures treated nonoperatively.^{52,53} Ultrasound treatment does not, however, appear to confer any additional benefit after intramedullary nailing with prior reaming. The discovery of specific bone growth factors (bone morphogenetic proteins [BMPs]) was an important step forward in the understanding of bone physiology and raised the possibility that these factors could be locally applied to enhance fracture healing. However, clinical trials have not yet determined the most appropriate indications for the use of BMPs in managing specific fractures or nonunions.⁵⁴

The indications for implant removal are not well established. There are few definitive data to guide the decision as to whether an implant should be removed or left in place. In general, implants in most adult patients may be left in place; the same is true of implants in the upper extremity. When implants are removed for relief of pain and mitigation of presumed functional impairment

alone, the results are unpredictable and depend on both the implant type and its anatomic location. Implant removal is often technically challenging and may lead to complications such as infection, neurovascular injury, or refracture. Current data do not support routine removal of implants to protect against allergy, carcinogenesis, or metal detection. The decision for or against implant removal is therefore based on individual patient and surgeon preferences, as well as on the clinical circumstances.^{55,56}

Management of Upper-Extremity Injuries

SHOULDER

Fractures of the clavicle are common and are usually caused by falling on the shoulder. Approximately 80% of clavicular fractures occur in the middle third of the bone, 15% in the lateral third, and 5% in the medial third. Dislocation results from traction of the pectoral and sternocleidomastoid muscles. Neurovascular injury is uncommon, but the patient should always be evaluated for such injury nonetheless. Treatment is primarily conservative, employing a collar and cuff or a sling; union rates approach 95%. Operative fixation is indicated only when there is impending perforation of the overlying skin, an associated injury to the subclavian artery and brachial plexus, an ipsilateral scapular neck fracture (so-called floating shoulder), a dislocation greater than 2 cm (a relative rather than absolute indication), or painful nonunion. Fixation methods include plate osteosynthesis and intramedullary osteosynthesis.⁵⁷

Scapular fractures result from high-energy trauma and are frequently accompanied by life-threatening injuries to the head, the chest, or the abdomen. CT scanning is usually required to determine the fracture pattern. Most scapular fractures can be treated conservatively. Severely ($> 40^\circ$) dislocated scapular neck fractures and dislocated intra-articular glenoid fractures are treated with open reduction and internal screw or plate fixation.

HUMERUS

Proximal

Fractures of the proximal humerus are common, especially in elderly women. Correct positioning of the four main bony structures of the proximal humerus (the head, the greater tuberosity, the lesser tuberosity, and the shaft) and their muscle attachments is important for a good shoulder function. Consequently, fractures of this segment of the humerus may have significant functional consequences. Damage to the blood supply of the head may lead to avascular necrosis of this part of the bone. Conservative treatment with a sling is preferred for elderly patients with minimally displaced fractures, and early range-of-motion exercises are encouraged. Operative treatment is indicated for patients with dislocated two-, three-, or four-part fractures and fracture-dislocations. The optimal fixation method has not been established, but plate osteosynthesis is frequently employed; alternatives include intramedullary techniques and prosthetic replacement.^{58,59} Rehabilitation usually takes several months, and continuing impairment of shoulder function is a common complaint.

Shoulder (glenohumeral joint) dislocations mostly occur in young persons participating in sports. The size difference between the large articular surface of the humeral head and the small surface of the glenoid renders the shoulder particularly vulnerable to dislocation. The majority (95%) of patients have anterior dislocations, resulting from abduction and exorotation. The relatively few posterior dislocations that occur tend to be difficult to diagnose and are frequently missed initially. A particularly rare and severe

type of shoulder dislocation is luxatio erecta, characterized by inferior dislocation of the abducted arm. Injuries associated with shoulder dislocation include injury to the axillary nerve, injury to the labrum (Bankart lesion), and a depression in the humeral head (Hill-Sachs lesion); the last two predispose to recurrence. Radiographs should be obtained in AP, axillary, and Y-scapular views to determine the position of the humeral head and detect any fractures. Treatment consists of gentle and closed reduction. This can usually be done in the ED; if necessary, it can be done in the OR with the patient under general anesthesia. Reduction is followed by immobilization in a sling.⁵

Dislocations of the sternoclavicular joint are rare, but they are potentially life-threatening when they occur posteriorly (anterior dislocations are far less dangerous). Diagnosis of these injuries is difficult with conventional x-rays; accordingly, CT is recommended when sternoclavicular joint dislocation is suspected. Compression of the mediastinal vessels and trachea can sometimes lead to respiratory and circulatory failure. In such cases, urgent operative reduction, performed with an eye to potential vascular emergencies, is warranted.^{5,10}

Dislocations of the acromioclavicular joint result from falling on the shoulder and are frequently classified according to the system formulated by Tossy. Tossy 1 dislocations (sprains) and Tossy 2 dislocations (subluxations) are treated conservatively with a collar and a cuff. For Tossy 3 dislocations (complete separations), operative treatment may be considered, though the optimal technique remains to be determined and the results of operative fixation are still uncertain.⁵

Shaft

Fractures of the humeral shaft typically result from direct trauma. Depending on the level of the fracture, dislocation mainly results from traction placed on the deltoid or pectoral muscles. Fractures of the middle and distal thirds of the humeral shaft can result in injury to the radial nerve, which is the most severe functional complication. Most closed AO-ASIF type A1 and A2 fractures can initially be treated conservatively with functional bracing techniques (rather than hanging casts); this approach yields good or excellent results in the majority of cases. Moderate angulation, rotation, and shortening are well tolerated. Generally accepted indications for operative treatment include open fractures, AO-ASIF type B and C fractures, associated vascular injury, multiple trauma, bilateral fractures, combined humeral shaft and forearm fractures (so-called floating elbow), pathologic fractures, secondary radial nerve palsy, and nonunion.⁶⁰ The standard technique is open reduction and plate fixation; the main alternative is locked intramedullary nailing, either antegrade (entering in the proximal humerus) or retrograde (entering in the distal humerus).^{61,62} External fixation is employed in the presence of severe soft tissue injuries and in polytrauma patients as part of DCS.

Distal

Fractures of the distal humerus result from falling on the elbow with the forearm flexed. In elderly persons, many of whom are osteoporotic, a fall from a standing position is often sufficient to cause such a fracture, whereas in young patients, high-energy trauma is required. Extra-articular injuries usually have a good prognosis. Intra-articular fractures are more difficult to manage: limitation of flexion and extension and pain often occur, even after optimal treatment. In addition to AP and lateral x-rays, it may be advisable to obtain CT scans to help clarify the fracture pattern. For minimally displaced AO-ASIF type A fractures, conservative treat-

ment is appropriate, but for all other fractures, open reduction and plate osteosynthesis are required, frequently in conjunction with an olecranon osteotomy to provide adequate exposure. In comminuted fractures, the articular surface can be difficult to reduce. In osteoporotic bone, finding good bone stock can be a serious problem.^{4,5,63,64}

ELBOW

Olecranon fractures are the most common fractures in the area of the elbow and usually are caused by falling directly on the elbow. They frequently lead to impaired extension as a consequence of the discontinuity between the triceps and the proximal ulna. All dislocated olecranon fractures are treated operatively, with Kirschner wires and a tension band employed for simple fractures and plate osteosynthesis for comminuted fractures. Both methods allow early functional therapy postoperatively.

Fractures of the radial head are caused by falling on the outstretched arm and may occur either in isolation or in combination with an elbow dislocation, an ulnar shaft fracture (Monteggia fracture), a coronoid process fracture, or a medial collateral ligament rupture. In addition, the interosseous membrane between the ulna and the radius may be disrupted over its entire length, thereby disturbing the distal radioulnar joint at the wrist (Essex-Lopresti injury). Fractures with dislocations smaller than 2 mm can be treated conservatively with early range-of-motion exercises; external support is usually unnecessary. Dislocated fractures and fractures causing mechanical blockage (e.g., of pronation or supination) are mostly treated operatively, with plate or screw fixation. When the fracture is comminuted, adequate reduction and fixation may be impossible. If the elbow is otherwise stable, radial head excision may be performed; if not, a radial head prosthesis may be inserted to stabilize the joint. Active and passive range-of-motion exercises should be started soon after the operation.
